mm and above reliably. Furthermore, it is also desirable to detect in situ carcinomas which usually grow within the ducts where they may extend within areas of very variable size. The ducts themselves, however, rarely exceed 1–3 mm in diameter and may be surrounded by uninvolved nonenhancing tissue. Hence with a tomographic imaging modality such as MRI it is important to minimize slice thickness so as to improve resolution and contrast.

In order to achieve sufficient signal-to-noise ratio, a dedicated single or double breast coil has to be used. Cardiac motion artifacts also need to be eliminated. At present, the best way to achieve the latter is by switching phase and frequency encoding gradients, so that the artifacts cross the axillas instead of the breast. An alternative is the use of coronal slices, where most of the artifacts neither cross the breast nor the axillas. (The use of local presaturation is not useful, since generally larger areas are extinguished than would be disturbed by artifacts. In our experience flow compensation increases echo time without sufficient effect on artifact elimination.)

In order to obtain sufficiently small slices without gaps, 3D imaging is strongly recommended. In this way it is possible, for example, to image the breast with 32 transverse slices of 4 mm slice thickness within slightly more than 1 min. By using a rectangular field of view and coronal slices, either the imaging time can be further reduced by a factor of two, or 64 slices of 2-mm slice thickness are possible within the same imaging time. Thus with present 3D techniques both high temporal resolution or high spatial resolution are possible.

However, when choosing between high spatial and high temporal resolution it should be remembered that with a 5-mm slice thickness in the worst case a 5-mm lesion may only be half contained within two neighboring slices. This means that only half of the signal increase can be measured in each neighboring slice. Hence 2-mm or thinner slices will probably allow better results, particularly with regard to the detection of intraductal enhancement. The optimum temporal resolution is still controversial.^{9–17}

As far as the choice of pulse sequences is concerned, the highest sensitivity to Gd-DTPA and hence the best contrast of enhancing lesions can be achieved with 3D gradient echo sequences such as FLASH or spoiled GRASS or with some fat saturation techniques like RODEO or spoiled GRASS with fat saturation.^{23–25} Due to their low sensitivity to Gd-DTPA, SE sequences can no longer be recommended.

Since enhancement might be confused with a fat lobule on the postcontrast image alone, elimination of the fat signal has been suggested as a means of improving the detectability of enhancing lesions. Elimination of the fat signal can be achieved in two different ways.

1. On T_1 -weighted fat suppression sequences, ideally only enhancing tissues display high signal intensity while dysplasia and suppressed fat exhibit low or no signal intensity. The disadvantage of fat suppression techniques is that they are more sensitive to magnetic field inhomogeneities. Within such inhomogeneities, which may be caused by the patient or the breast coil, enhancement might be underestimated or missed. Thus, greater technical prerequisites need to be fulfilled, i.e. more experience and very careful quality control are necessary.

2. Since fat does not enhance, like all other nonenhancing tissues it is ideally eliminated on subtraction images. Software has now been developed which allows routine subtraction of

all corresponding pre- and postcontrast slices (2×64 slices) within about 1 min. The major disadvantage which has been ascribed to this technique relates to problems which occur when the patient moves. In our experience, this problem occurs with less than 5–10% of all patients with currently available very short imaging times. Motion and its inherent problems are at least readily recognized with this technique.

Three-dimensional MIP reconstruction is possible for both fat suppressed and subtracted images. It has been suggested as a means of improving the distinction of enhancing vessels from enhancing ducts.²⁷

As far as optimum dosage is concerned, to date only one dose comparison study has been published.²⁸ In this study, we demonstrated that significantly better results were obtained with FLASH-3D using the higher dosage of 0.16 mmol of Gd-DTPA per kg as compared with the widely used lower dosage of 0.1 mmol of Gd-DTPA per kg. In fact, three out of 54 carcinomatous foci would have been overlooked with the lower dosage. Histologically, these three foci were all smaller than the applied slice thickness of 4 mm.

3.3 Results

The results of CE MRI of the breast are based worldwide on the examination of over 5000 patients.^{6–28} Despite still remaining differences in technique and image interpretation, the following results have been confirmed: (a) the great majority of invasive carcinomas are enhanced (see Figure 2); (b) no significant enhancement is usually seen in normal breast tissue, in nonproliferative dysplasia, sclerosed benign tumors, old scarring, and cysts; and (c) variable enhancement, which might cause false positive calls, has been encountered in some proliferative dysplasias, in nonsclerosed benign tumors, and in inflammatory changes.

In over 700 biopsy-proven tissues which we have examined with FLASH-3D, about 75% of the dysplasias enhanced only a little and it was possible to define a threshold so that all carcinomas enhanced more than by this threshold.^{16,17}

We also evaluated the shape of enhancement and roughly estimated the speed of enhancement in these 700 tissues. In a similar manner to mammography, we found that an irregular

outline of an enhancing lesion was indeed highly suggestive of malignancy, but neither diffuse nor well-circumscribed enhancement could reliably exclude malignancy (for example, 16% of the diffusely enhancing tissues and 21% of our post-operatively examined well circumscribed lesions, in fact, turned out to be malignant). When the speed of enhancement was estimated from two postcontrast studies (first measurement: 1–5 min post injection; second measurement 6–11 min post injection), fast enhancement was highly suggestive of malignancy but unfortunately delayed enhancement could not rule out malignancy reliably. This result has been confirmed by another separate dynamic study in 79 patients, where selected slices were imaged every 30 s after i.v. injection of Gd-DTPA.^{7,16,17}

As to the potential of dynamic contrast studies, controversial results are still being discussed. While Kaiser^{9,10} reports a sensitivity and specificity of 97% with dynamic contrast-enhanced MRI, other authors have not been able to reproduce these results, reporting both fast enhancing benign tissues and (what is much more important) slowly enhancing malignancies.^{12–17} In our experience the use of a slow enhancement speed as a criterion of benignity is comparable to increasing the threshold above which enhancement is considered to be possibly malignant, i.e., specificity can be improved at the cost of sensitivity.

Since the development of very fast pulse sequences such as Turbo-FLASH or echo planar imaging, it has become possible to image the first pass of a contrast agent within a tissue. Initial results with Turbo-FLASH have been promising.²⁶ The optimum use of this additional information needs to be carefully determined, in view of its effect on both sensitivity and specificity. When the results of various authors are compared^{6–28} (Table 1), excellent sensitivity values overall have been reported for CE MRI. Indeed, the sensitivity exceeds that of conventional imaging. Differences can be explained by different techniques (sometimes thick slices with gaps, the choice of pulse sequence, the dosage of Gd-DTPA), by different guidelines for interpretation, and by different patient selection. On comparison with conventional imaging alone, the sensitivity was however, improved in general. This diagnostic gain was, however, most prominent within mammographically dense and/or distorted tissue, while in fatty breasts and in cases with microcalcifications little or no diagnostic gain was achieved.

Table 1 Sensitivities and Specificities of Enhanced MRI, as Reported in the Literature

Author	Year	Sensitivity of MRI (%)	Specificity of MRI (%)	Sensitivity of Conv. ^a (%)	Specificity of Conv. ^a (%)
Allgayer (1) ^c	1991	90	40	ni	ni
Fischer (2)	1992	95	89	ni	ni
Gilles (3)	1993	93.3	63.1	ni	ni
Harms (3)	1993	94	37	ni	ni
Heywang-Köbrunner (1)	1993	98.6 ^b	65.0	60	45
Heywang-Köbrunner (3)	1993	99.5 ^b	28.0	82	18
Kaiser (1)	1992	97 ^b	97	ni	ni
Lewis-Jones (1)	1991	100	91	100	60
Oellinger (4)	1993	88	80	83	75

^aConv. = Sensitivity/Specificity of conventional imaging.

^bSensitivity/Specificity based on MR and conventional imaging.

^c(1), problem cases; (2) retrospective study; (3) preoperative patients; (4) evaluation of multicentricity.

ni = not indicated.

Figure 2 Mammography versus MRI in cases of very dense breasts. (a) Mammography of a 43 year old patient, cranio-caudal view. Very dense right breast, no radiological evidence of malignancy. (b) MR image before injection of the contrast agent; anatomical region of the upper quadrants. Basically fatty tissue and small areas of parenchyma in the upper inner quadrants of both sides. (c) MR image after application of the contrast agent gadolinium-DTPA with moderately strong signal intensity rise in the parenchyma of the inner quadrant of the patient's right breast (see arrow). Same position as in the precontrast MR image shown in (b). (d) The use of the subtraction method (postcontrast minus precontrast) allows the postcontrast enhancement of carcinomas to be seen much better. This method is especially useful in the case of small carcinomas. The histology revealed an invasive ductal carcinoma

With respect to microcalcifications and in situ carcinomas, the following may be stated. Mostly due to patient preselection, experience concerning the capabilities of MRI in this field is still limited to date. Some authors reported misses. Although our in situ carcinomas did enhance, some did so diffusely and many slowly. Thus, detection of in situ carcinomas and their differentiation from proliferative dysplasias is certainly also a question of threshold and interpretation. Those 50–60% of in situ carcinomas which contain microcalcifications are already excellently visualized by mammography. Even though improvement of the mammographic specificity in this field is still desirable, we do not recommend MRI in this case for the following reasons:

1. It is not known as yet whether all in situ carcinomas are sufficiently vascularized to be detectable by contrast-enhanced MRI.
2. Further research must show whether in situ carcinomas can be included in the enhancement thresholds of MRI without risking too many false positive calls. In our own experience, numerous false positive calls occurred particularly in cases with mammographic microcalcifications.
3. Due to the additional possibility of partial volume effects, excellent thin slice techniques will be necessary together with extremely careful application of any threshold.

Thus, we do not recommend reliance on MRI in this field at present and we do not recommend application of MRI as a means of answering these questions. Instead diagnostic decisions should be based on careful analysis of the mammogram and possibly other diagnostic tests such as transcutaneous biopsy.

As far as noncalcified in situ carcinomas are concerned, it is important to mention that seven out of our 21 in situ carcinomas were detected by MRI alone. The in situ carcinomas detected by MRI frequently became apparent as a focal area of enhancement and sometimes enhancement with a ductlike shape.

While the sensitivity results of CE MRI have been very satisfying, improvement of specificity has been a major concern (Table 1). Overall the following possibilities are being discussed:

(i) All available information including that of shape and speed of enhancement should be used for the final diagnosis. Because of the existence of both diffusely and slowly enhancing carcinomas, it is necessary to warn against overinterpretation of shape or speed of enhancement. Optimization of interpretation guidelines in this field (using optimum techniques) will therefore be an important task for the near future.

(ii) In addition, all available information including that of mammography and clinical examination should be used for the final diagnosis. MRI is not a stand-alone method!

(iii) In order to avoid unnecessary biopsy of MR-detected small benign enhancing lesions, MR follow-up of benign-appearing lesions (predominantly well-circumscribed round or oval lesions, which are likely to be small fibroadenomas) is recommended. MR-guided stereotaxic transcutaneous biopsy should be considered for indeterminate benign-appearing lesions. First experiences with such devices are presently being acquired.

(iv) Finally unnecessary costs should be avoided and optimum diagnostic gain attempted by using MRI exclusively for those indications where definite advantages compared with conventional imaging can be expected.

On the basis of our own experiences over 2000 contrast-enhanced MR studies of the breast, we do not recommend contrast-enhanced MRI for the following indications: (a) evaluation of microcalcifications (see above), and (b) evaluation of those cases where diffuse enhancement is to be expected in any event, since in these cases malignancy can never be excluded in principle. Such cases include clinically obvious inflammatory changes, patients with secretory disease, and patients with known enhancing dysplasia from previous studies.

As an additional method however, CE MRI has been most helpful in diagnostic problems within mammographically dense or distorted tissue. Most interesting indications in these breasts include the search for primary tumors (not detected by conventional imaging) and the exclusion of multicentricity or contralateral involvement in patients with small tumors and very dense tissue (see Figure 2).^{15–17,24} Contrast-enhanced MRI is particularly useful for patients with severe scarring after surgery, after radiation therapy, and after silicone implant.^{16,20–22} It must, however, be added that MRI should not be used within the first 3–6 months after surgery or within the first 12 months after radiotherapy (RT), since post-therapeutic diffuse enhancement usually impairs evaluation during that period.

3.4 Conclusions and Outlook

The use of a contrast agent is obligatory for MR detection and diagnosis of malignancy. Contrast-enhanced MRI is gaining increasing importance as an additional tool for breast diagnostics. However, because of the increasing interest in the method, optimization and standardization of interpretation is an urgent task for the near future.

In order to develop optimized criteria for interpretation, an international multicenter study is presently being started. The study is supported by Siemens Corporation, Schering, and Berlex Corporations, and includes only centers with a high reputation in both breast imaging and MRI based on histologically proven data only. Both the optimization of interpretation guidelines, and in a second prospective trial the determination of wellfounded and generally recognized accuracy data, are the major goals of this study. These data, as well as further research by other groups, will help to define the optimum role which MRI should play in integrated diagnostic work-up.

MRI is thus gaining its place in breast diagnostics. It must be our concern to use MRI optimally only for those indications where definite diagnostic gain can be achieved for the patient without risking false negative calls and without causing an unacceptable number of false positive calls, which might cause unnecessary concern, costs for additional clarification, or even surgery. Further development and improvements of the technique are still proceeding.

Cardiac Gating Practice

David N. Firmin

National Heart and Lung Institute, University of London, UK

1 INTRODUCTION

Conventional magnetic resonance images or spectra are acquired over a period that is much longer than the cardiac cycle and for this reason some method of referencing to the cardiac cycle is required. If cardiac images or spectra were to be acquired without any reference to the cardiac motion, then the position of the heart would vary from one view or signal acquisition to another and artifacts and blurring of the image or signal contamination of the spectrum would result. Although the referencing techniques are often referred to as cardiac gating, strictly speaking they would be better referred to as cardiac synchronization. Gating is a technique used in radio-nuclide ventriculography, for example, when the acquisition occurs continuously but the cardiac events are used to time the opening and closing of an acquisition 'gate' or 'gates', so that the image or images that are built up relate to specific parts of the cardiac cycle.

There have been two approaches to cardiac synchronization of the MR acquisition: the first, known as prospective cardiac gating or cardiac triggering, was initially developed and used for early cardiac MR scanning and can be used for any type of MR imaging sequence. The second, known as retrospective gating, has been developed for synchronizing fast repetition cine acquisitions to the cardiac cycle. Both techniques have their own advantages and disadvantages as will be discussed below.

2 REQUIREMENT OF CARDIAC GATING

The importance of synchronizing the MR acquisition to the cardiac cycle is illustrated in Figure 1 which shows an example of spin echo images of the heart acquired with (a) and without (b) cardiac triggering. In this case, lack of gating generates artifacts resulting from view-to-view variations in the position of the heart and blood flowing through it. Cardiac synchronization is not only important for cardiac imaging; other organs in the body pulsate due to pressure changes in the arterial vascular systems and image quality has been shown to improve with cardiac gating. Single shot techniques such as echo planar imaging, where the acquisition time is relatively short in comparison to the cardiac cycle, require cardiac triggering when the relationship between the image and the time in the cardiac cycle is of interest, as would be the case for echo planar imaging of the heart.¹ Also for imaging of the spinal cord where CSF pulsates with the cardiac cycle² and techniques such as diffusion imaging³ are particularly sensitive to motion, some form of cardiac triggering or gating is required.

3 METHODS OF CARDIAC MONITORING

There have been a number of approaches to monitoring the cardiac cycle including various forms of pulse sensor, the electrocardiogram (ECG), and magnetic resonance methods of rapidly imaging the position of the heart. The pulse sensors include those that monitor the changes in infrared reflection or absorption in the vascular bed and are normally placed on the finger or the ear lobe and continuous wave Doppler probes directed at any 'near surface' artery. Both of these methods monitor the pulsatility of blood flow and can be set up to detect the slope or the amplitude of the waveform. In general, pulse sensors are not used unless the electrocardiographic waveform is unusable. The main problem with the methods are that timing errors can occur, both because the waveforms are less well defined than the ECG, in that there are no high-frequency portions to compare with the QRS complex, and because physiological factors can affect the shape of the waveform. An additional problem is that there can be a significant delay between the beginning of cardiac contraction and the associated flow pulse that is being detected. One advantage, however, is that the signal is affected less by the static magnetic field, and the rf and gradient pulses that can interfere with the ECG waveform; the latter two are problematic, especially when sequences are repeated very rapidly.

The safety implications are similar for ECG and pulse sensor monitoring although the hazards are somewhat greater for the ECG system because of the requirement of electrical contacts made directly to the skin. It is possible for the transmitted rf signal to be coupled into the leads of the system to such an extent that their temperature is raised enough to cause local burning. To avoid this risk, large loops are avoided and the leads are kept away from the patient's skin as much as possible.

Transmission of the electrocardiogram out of the magnet also requires care as cables running out of the magnet can act as an aerial and transmit radiofrequency noise into the scanning region. To overcome this, the electrocardiogram can either be converted to an optical signal and carried out along a fiber-optic cable⁴ or transmitted by radiotelemetry at a frequency that does not interfere with the MR signal.⁵ In 1990, Spraggins described a method of cardiac gating that required no external monitoring device. The method involved alternating between the acquisition of image and timing data, the latter being non-phase-encoded and designed to give a 1D image to monitor the changing size of the heart, that could later be used to reorder the image data retrospectively.⁶

4 ARTIFACTS ON THE ELECTROCARDIOGRAM

Recording an electrocardiogram in a magnetic resonance scanner during a scan is not a simple matter and the waveform bears little relationship to the one that would be obtained away from the magnetic field. The static field has a number of effects, and the changing gradient and rf fields applied during the imaging introduce additional artifacts. The flow of blood (a conductor) through the heart and great vessels in the presence of the static magnetic field results in a varying induced potential that is superimposed on the electrocardiogram. The main effect is during the systolic part of the heart cycle when blood

Figure 1 Illustration of the importance of cardiac gating when imaging the heart. The figure compares transverse spin echo images of the heart (a) ungated and (b) gated to the end-systolic part of the cardiac cycle

is flowing most rapidly out of the heart and in the aorta, and the size of the T wave is most noticeably affected. The effect is governed by the Faraday–Neumann law which states that if a conductor cuts a magnetic flux, ϕ , the induced potential difference, V , is proportional to the rate of change of flux, $d\phi/dt$, so that the effect is greatest when there is a large component of flow perpendicular to the field (crossing lines of flux); the direction of the induced potential is perpendicular to both of these. The size of the potential is also directly related to the strength of the magnetic field so that the artifacts are much more pronounced at high field strengths. As far as the detection of the QRS complex of the electrocardiogram is concerned, generally the detection systems monitor the rate of change of the signal and not the overall amplitude. Even though the increased T wave is accompanied by an increased rate of change of the signal, the rate of change found during the QRS complex is normally significantly greater. Another

artifact caused by the presence of the static magnetic field is that of induced potentials that result if the ECG leads are moved during the scan. Some care is required to choose electrode sites that minimize the potential of such a problem.

The switched magnetic field gradients that are used during all imaging sequences also introduce rapidly changing potentials that can severely interfere with the electrocardiogram. The size of these depends on the rate of change of magnetic flux through the conductor loop presented to the field and upon the area of the loop. The size of the artifacts can be reduced, therefore, by twisting the cables up to the patient and placing the electrodes close together. The latter of these is somewhat self-defeating in that placing the electrodes closer together also reduces the amplitude of the detected QRS complex. Most ECG amplifiers that are used in MR systems are modified so that they detect the rapidly changing potentials and clamp or hold the waveform for their duration. For the majority of magnetic resonance sequences, this allows the ECG waveform to be monitored as the gradient switching occupies a relatively small proportion of time. However, for very fast sequences such as echo planar imaging, the gradients are switched so rapidly that the waveform is obscured throughout the acquisition.

The radiofrequency pulse may also cause problems if it couples into the ECG leads or amplifier circuitry. Some amplifier systems are controlled by a microprocessor and such systems have to be very well shielded from the rf to avoid signal disruption.

5 ELECTROCARDIOGRAM ELECTRODE AND LEAD POSITIONING

There are a number of factors that are relevant when choosing the positions to place the ECG electrodes. These factors include the requirement to get a good reliably detectable QRS signal, to minimize artifacts due to breathing, to minimize the potential for artifacts on the image due to the metallic content of the ECG electrodes, and to minimize any potential coupling between the rf signals and the cables of the ECG system.

Dimick and colleagues have shown that the vector of the blood flow induced potential normally points anteriorly and slightly down the body.⁷ The QRS complex vector, on the other hand, usually points to the left, posteriorly and down so that a left-sided or posterior lead is recommended to maximize the ratio between this signal and the artifactual one. One approach that is used to achieve this is to place the two active electrodes one on the right shoulder and the other on the lower left side of the chest, with the common electrode often positioned on the left shoulder (Figure 2). An alternative is to place the electrodes in similar positions on the back; although the detected signal is not quite as strong, the potential for motion artifacts due to respiration are reduced.

The material of which the electrodes and cables are made is also relevant. These are not normally ferromagnetic, but their metallic content can induce artifacts by altering the magnetic field locally. In spin echo imaging the artifacts are very superficial and can normally be ignored, but field echo images are much more affected (Figure 3). Positioning of an electrode or lead over the region of interest should therefore be avoided unless specialized electrodes and leads containing minimal or no metal (i.e. carbon compounds) are used.

Figure 2 Typical positions of the electrodes for recording the electrocardiogram during magnetic resonance imaging. Similar positions on the back can be used, at the expense of a weaker signal, to reduce motion artifacts due to respiration. 6 PROSPECTIVE AND RETROSPECTIVE GATING

Both prospective and retrospective forms of gating involve monitoring the ECG or other cardiac-related signal with the regular detection of a prominent part, such as the QRS complex of the ECG or the arterial flow pulse of a pulsometer waveform.

With the prospective system, the detection is used to initiate one or a number of sequence repetitions following a predefined delay and separated by a repetition time TR [Figure 4(a)].^{4,8} The sequence repetitions can be of the same phase encoding acquisition for a number of different slices, the same phase encoding acquisition for a number of frames from a cine scan, or a number of different phase encoding acquisitions contributing towards one image. If the sequence can be repeated very quickly, then a complete image can be acquired within a fraction of a cardiac cycle; in this case, a delay is used following the cardiac detection to the start of the sequence repetitions to define the period of the cardiac cycle over which the image is acquired. For extremely fast techniques such as echo planar, several images can be acquired within a cardiac cycle and, rather as for the phase encoding steps of the slower methods, either multiple slices or multiple cine frames can be acquired at defined times following the cardiac detection.

One problem with this prospective method of triggering is that of cardiac arrhythmia, which invalidates the assumption that the cardiac cycles used to construct the image are identical. Artifacts can result for two different reasons: firstly the position and shape of the heart may vary from beat to beat, and secondly the time between excitation can be different from one beat to the next, a fact that can cause an amplitude modulation of the acquired signal. In practice, however, normal sinus arrhythmia and infrequent ectopic beats of the heart do not seriously inter-

Figure 3 Artifacts produced by metallic electrocardiogram electrode positions on the chest near the apex of the heart (large arrow). On the spin echo image (a) the artifacts are very much smaller than on the gradient echo image (b). (Reproduced by permission of Blackwell Scientific Publications, from 'Magnetic Resonance of the Cardiovascular System', ed. S. R. Underwood and D. N. Firmin)

fere with image quality. For cine field gradient echo imaging, however, the enforced requirement to leave a period of delay between the last frame and the next trigger results in a relatively high signal (sometimes known as the lightning artifact) on the first frame of the cine because of the increased longitudinal relaxation that occurs during the delay. This also means that part of the heart cycle cannot be imaged, this being the end-diastolic part when using the R-wave of the ECG as a trigger.

The retrospective method of cardiac gating was developed to enable cine field echo images to be acquired throughout the entire cardiac cycle, to remove the lightning artifact and to reduce the other artifacts that result because of cardiac arrhythmia.⁹⁻¹¹ The method involves the continuous repetition of the sequence at a constant TR whilst also monitoring and recording a cardiac waveform. There are two ways of implementing the technique: firstly by advancing the phase encoding at a regular

Figure 4 Diagram comparing the different methods of cardiac gating for a cine acquisition. Cardiac triggering (a) cannot adequately cover the diastolic part of the heart cycle and has a variable delay between the last frame on one heart cycle and the first frame of the next. For the first retrospective gating method (b) the phase encoding is incremented at regular intervals that are ca. 20% longer than the average cardiac cycle. The majority of heart cycles are therefore oversampled and data for one phase encoding may well be made up from two different heart cycles. For the second retrospective gating method (c) the phase encoding is incremented on the fly immediately after the R wave detection

interval that is longer than the longest cardiac cycle [Figure 4(b)] or secondly by changing the phase encoding step immediately after each cardiac detection [Figure 4(c)]. The first method is the easier to implement; the cardiac cycle is monitored for a period of approximately 30 s and the mean cardiac cycle duration calculated. Then, from the TR of the predefined cine sequence, the number of time frames that will fit into the mean cardiac cycle plus 20% is calculated; the phase encoding is then stepped regularly after this number of frames. The phase encoding steps now occur at arbitrary times in the cardiac cycle and data reordering is necessary before image reconstruction. The disadvantage of this approach is that the scan time is

Figure 5 Diagram to illustrate how retrospective gating with data interpolation can be used to compensate for the nonproportionate variability in the cardiac cycle. The reconstructed systolic frames have a constant TR whereas for the diastolic frames the TR is varied

extended by approximately 20% and the data for particular phase encoding steps are likely to be acquired over two different cardiac cycles. The second method of retrospective gating overcomes these problems: the phase encoding gradient is incremented immediately after each cardiac detection and, depending on the cardiac duration, a variable number of sequence repetitions and data acquisitions may be employed for each phase encoding gradient. The technique requires very flexible hardware enabling the phase encoding gradient to be incremented on the fly, an option not available on the majority of systems.

Both retrospective methods require data interpolation to reconstruct a defined number of images within the cardiac cycle at time points that may lie between those that were actually acquired. Normally, simple linear data interpolation is used although least square interpolation schemes using variable time windows have been investigated; the wider the time window the higher the S/N, but the greater the temporal averaging and consequential image blurring. The simple interpolation method is generally acceptable if image frames are acquired with a reasonably high temporal resolution. The fact that the cardiac cycle varies in a nonproportionate manner, such that the systolic part varies in length less than the diastolic part, can be taken into account with this method of interpolation before reconstruction (Figure 5).

A heart in atrial fibrillation or exhibiting frequent ectopic beats can present a problem for either prospective or retrospective gating, although for cardiac triggering and the second

Figure 6 Arrhythmia rejection. The user defines a window of beat lengths that will be accepted. The data acquisition on the beat following one that falls outside this window is rejected and the effect is to reject the acquisition of the ectopic beat and the following sinus beat. (Reproduced by permission of Blackwell Scientific Publications, from 'Magnetic Resonance of the Cardiovascular System', ed. S. R. Underwood and D. N. Firmin)

Figure 7 Illustration of the methods of acquiring velocity encoded data with retrospective gating. The velocity encoding is normally alternated on successive acquisitions (a); however, this can result in some high-frequency filtering of the pulsatile flow waveform. Alternating the velocity encoding after a fixed number of phase encoding steps removes the problem but is inefficient (b), and efficiency can be improved by alternating velocity encoding on the fly on successive cardiac cycles (c)

method of retrospective gating it is possible to suspend data acquisition and incrementing the phase encoding for a number of beats after a cycle of abnormal length (Figure 6).

7 IMPLICATIONS OF THE GATING TYPE ON THE ACCURACY OF BLOOD FLOW MAPPING

The potential of magnetic resonance to measure blood flow is of particular importance to studies of the cardiovascular system. Although many techniques have been described, the

method of phase velocity mapping¹²⁻¹⁴ has been shown to be particularly useful clinically.¹⁵ The method of gating has been shown to have implications on the accuracy of pulsatile blood flow measurement using phase velocity mapping.^{16,17}

The phase velocity mapping technique, when used to measure flow in a particular direction, involves the simultaneous acquisition of two scans with a different phase sensitivity to velocity in that direction. Phase images are reconstructed and these are subtracted to form the phase velocity map. When prospective gating is used, the data are acquired for the different velocity sensitivities on successive cardiac cycles. This enables high temporal resolution flow data to be acquired throughout the majority of the cardiac cycle. With retrospective gating, in order to minimize the scan time, a method of alternately acquiring the different velocity sensitivity data on successive sequence repetitions has been used [Figure 7(a)]. This has the effect of doubling the *TR* of the sequences and has been shown to result in a high-frequency filtering of the pulsatile blood flow waveform. Methods of reducing or removing this error include using a shorter *TR*, minimizing the interpolation window, and running two separate scans with the order of velocity encoding reversed before resorting the data appropriately.¹⁶ Alternatively, the method of acquisition could be changed so that the velocity sensitivity of the sequence is changed less frequently, on successive cardiac cycles or on successive periods 20% longer than the mean cardiac cycle, depending on the method of retrospective gating that is being used [Figure 7(b) and (c)].

Cardiovascular NMR to Study Function

Donald B. Longmore

Royal Brompton Hospital, London, UK

1 INTRODUCTION

Approximately half of those reading this volume will die of cardiovascular disease, a further quarter will die of cancer, and 12% of lung disease. The diagnosis of these diseases are all now within the capabilities of NMR. However, vast intellectual and financial resources have been, and are being, applied to magnetic resonance technology, ignoring these major causes of death. Only a handful of the world's 9800 NMR machines are available to cardiologists, oncologists, and lung specialists. Presently NMR is used to study less than 3.5% of all disease. Open access rapid cardiovascular and lung imagers with facilities for intervention including laser and ultrasound surgery are technically feasible and needed urgently. Furthermore, the diagnostic power and, from the patient's point of view, the simplicity of a functional cardiovascular NMR examination, means that, for the first time, the ultimate medical objective of preventing the commonest diseases could be realized. The potential of functional evaluation of the cardiovascular system is for population screening to enable an understanding of the natural history of atheromatous disease, the commonest cause of death in the western world. Detection of presymptomatic cardiovascular disease enables both secondary prevention monitoring the efficacy of therapeutic and preventive measures using repeated functional NMR studies. Demographic evidence reveals the changing incidence of the disease in the same population over time and the varying incidence from place to place in the same ethnic groups (see section 8). This, coupled with experimental evidence, shows atheroma to have causative factors—and therefore to be preventable.¹⁻⁴ While the heart and circulation are being studied, it is only a small step to include screening for breast cancer⁵ (*Breast MRI*) and, with the new ultra-short (50 μ s to 500 μ s) *TE* sequences, to study the lung (*Lung and Mediastinum MRI*).

Contemporary cardiovascular diagnosis relies on an expensive and time-consuming combination of clinical examination, chest radiography, electrocardiography (ECG), stress ECG, echo cardiography, nuclear medicine studies with and without pharmacological stress and invasive cardiac catheterization, which carries a small but important mortality and morbidity. Unsuccessful attempts have been made to evaluate the cardiovascular system avoiding cardiac catheterization using external recording devices such as apex cardiography, ballisto cardiography, ECG, impedance cardiography, etc. Now the balance has been profoundly altered following advances in nuclear medicine techniques, X-ray computed tomography, and echo cardiography. NMR is the most powerful diagnostic instrument yet conceived and this, combined with echo cardiography,

means that virtually every cardiac diagnosis that previously required invasion can now be made noninvasively and cost-effectively, without mortality or morbidity. Until recently the exception was coronary artery disease. The NMR alternative to the coronary angiogram is dealt with elsewhere.

2 TECHNICAL REQUIREMENTS FOR CARDIOVASCULAR NMR

In order to study cardiovascular function, magnetic resonance techniques additional to those for imaging motionless parts of the body are required. Essential enhancements are cardiac gating, velocity mapping (*Cardiac Gating Practice*), rapid imaging, and velocity encoded rapid imaging (*Whole Body MRI: Strategies for Improving Imaging Efficiency*) in all planes.⁶⁻⁸

2.1 Imaging Strategy

A comprehensive heart NMR study is achieved in minimal time using a simple strategy. A transverse (transaxial) image of the chest is used to measure the angle of the heart to the left. A scan in the plane through the long axis of the left ventricle produces a vertical long axis (VLA) image through the left atrium and the left ventricle. From this, the downward angle of the heart is measured and a double oblique image from below produced to provide a horizontal long axis (HLA) view [Figure 1(a)] showing the five functional chambers of the heart and the coronary arteries in cross-section. Image planes can be selected perpendicular to the HLA to produce the short axis (SA) image [Figure 1(b)].

Figure 1 (a) The spin echo HLA image shows the right atrium (RA), the right ventricle (RV), the left atrium (LA), the left ventricle (LV) and the left ventricular outflow tract (O). The tricuspid valve which is not indicated is at the same level as the mitral valve marked (MV). The right coronary artery (RCA) and the left coronary artery (LCA) are also seen in cross-section. Fat at the apex of the heart is prominent. (b) The spin echo SA image shows the 'doughnut'-shaped left ventricular muscle (LV) with the right ventricle (RV) anterior to it. The left anterior descending coronary artery (LAD) is seen in the upper interventricular groove and the coronary sinus (CS) in the lower interventricular groove

2.2 Rapid Imaging applied to the Cardiovascular System

Two rapid imaging techniques are currently available^{9,10} (dealt with in detail in *Blood Flow: Quantitative Measurement by MRI*). Orders of magnitude of reduction of acquisition times for NMR imaging were first achieved by Mansfield and Pykett⁸ with the one-shot echo planar 'Snapshot' (EPI) technique. The advantage of EPI for the cardiovascular system is that data acquisition can follow preparation pulses required to study cardiovascular function for diffusion, chemical shift imaging, and velocity encoding. The alternative to EPI with velocity mapping is the fast low angle shot (FLASH) technique with velocity mapping. EPI has a better signal-to-noise ratio (SNR) and can freeze movement, which is vital in the neonate. Less than 50 ms acquisition time is needed to obtain a velocity encoded image. The FLASH technique uses a total acquisition time of over 300 ms. There is no stage in the cardiac cycle of an infant when the heart is relatively still for this long. Furthermore, at all stages throughout life the filling and contraction of the heart varies from beat to beat. This variability is never more marked than in the neonate with congenital disease. EPI is more suitable for the measurement of aperiodic movements (irregularly irregular) than FLASH, which relies on periodicity and the heart being in the same position and at the same stage of contraction for 16 or more heart beats. However, despite these disadvantages, because the gross appearance of a FLASH image is mainly determined by the data from a relatively few central phase encoding steps acquired in the first 50 ms or so of a total acquisition of over 300 ms, acceptable FLASH velocity encoded imaging is possible; FLASH is also less demanding on the gradients, the rf, data collection, etc., and it can be implemented on standard machines with relatively simple modification.

Either technique can be used to find a jet, measure its velocity and, from the velocity measurement, calculate the gradient and therefore the severity of the lesion using a modified Bernoulli equation.¹¹ Velocity mapping combined with good anatomical imaging usually reveals more useful functional information about congenital and acquired disease than can be obtained from a cardiac catheter angiogram.

2.3 Volume Measurements

The volumes of all the cardiac chambers, notably the ventricles, can be measured accurately from two multislice sets of transverse, or HLA, or SA images, one set taken at end systole (when the volumes are least) and the other at end diastole (when the heart is fullest). Usually 10–12 slices are sufficient to cover the whole of the heart. The areas of the cardiac cavities can be measured manually or by automatic edge detection or area growth techniques. Ventricular volume measurements are obtained by summing the areas of the images covering the ventricles in systole or diastole. The thickness of the slices is known and the volume of each slice calculated. Summation of the various slice volumes gives the total cavity volume.¹²

A 'shorthand' method of measuring stroke volume uses area length calculations of VLA and HLA systolic and diastolic images assuming the ventricles to approximate to a cone. The end diastolic volume is calculated from the formula:

$$\frac{\text{area of diastolic VLA} \times \text{area of diastolic HLA}}{\text{minimum diastolic length apex to valve plane}} \times 0.85 \quad (1)$$

and the end systolic volume from the formula:

$$\frac{\text{area of systolic VLA} \times \text{area of systolic HLA}}{\text{minimum length apex to valve plane}} \times 0.85 \quad (2)$$

This method is only valid if the ventricles are contracting evenly.

2.3.1 Clinical Significance of Volume Measurements

Subtraction of the systolic volume from the diastolic volume produces an accurate measure of stroke volume, which when multiplied by the heart rate gives the cardiac output. Continued life depends on the way the heart is functioning rather than on the output at a moment in time. An efficient heart retains a small residual volume of blood which when compared with the stroke volume gives the ejection fraction. A low ejection fraction carries a poor prognosis.

2.3.2 The Four Way Comparison

Volume measurements have been validated by comparing the stroke volumes of the right and left ventricles which in normal subjects is unity. The stroke volumes have also been compared with the aortic and pulmonary artery flows. Three measurements (right ventricular output, pulmonary artery flow, and left ventricular output) correspond to within 2%. Aortic flow is 5–10% below the other measurements due to the 'take off' of coronary flow.

Functional assessment of the cardiovascular system can be applied to all types of disease. In this article the classical 'surgical sieve' is used, dividing disease into congenital and acquired, and further dividing acquired disease into traumatic, inflammatory, neoplastic, etc. There is a 'gray area' where it is difficult to distinguish between diseases we are born with and those we acquire, possibly because we are genetically vulnerable.

3 FUNCTIONAL ASSESSMENT OF CONGENITAL HEART DISEASE

Approximately three in every 1000 live births manifest one of the commoner congenital heart diseases, pulmonary artery stenosis, atrial septal defect, patent ductus arteriosus, and tetralogy of Fallot, though there is a significant incidence of many other complex forms of congenital disease. NMR functional imaging can detect and quantify the threat to life and form a vital part of the management in all these conditions. Three discrete groups of patients require functional assessment. These are: neonates and infants; children, when the less catastrophic abnormalities begin to manifest themselves; and 'grown up' congenital heart disease usually to follow up the results of surgical intervention.

3.1 Neonates and Infants

The small size of an infant and its inability to lie still, combined with the complexity of many congenital abnormalities,

necessitates a rapid imaging technique and the use of special surface coils or a head coil.

3.2 Functional Imaging in Children

Functional techniques have given an insight into the compensatory mechanisms which can allow an infant with gross cardiac abnormalities to survive to childhood when operative intervention is easier and safer. The ideal diagnostic techniques for children are a combination of rapid imaging used in neonates and infants and the standard adult functional imaging methods.

3.3 'Grown Up' Congenital Heart Disease (GUCH)

NMR is the only available technique for the repeated long-term follow-up of adolescents and young adults who have undergone successful surgery. It is vital in postoperative cases to include velocity mapping searching for deterioration, because calcified obstructions are not visualized on anatomical images and can only be demonstrated by blood velocity mapping.¹³

NMR is uniquely able to detect the afferent and efferent vessels to congenital arteriovenous (AV) malformations, helping the surgeon to plan an operation. In cases with multiple AV malformations (Klippel, Trilawney syndrome) the measurement of the total blood flow through all the afferent or efferent vessels to the AV malformations can predict the impending onset of high-output heart failure.¹⁴

3.4 The Late Effects of Congenital Heart Disease

3.4.1 Valve Disease

Valve disease may be acquired or present as a late manifestation of congenital heart disease. A small proportion of the population are born with a bicuspid aortic valve which will usually function normally until the patient reaches the fourth decade of life, by which time calcification causing stenosis and regurgitation results from the abnormal vibrations and stresses on the two cusps. NMR can be used to measure the jet velocity and to calculate the gradient and to measure the regurgitant fraction. This regurgitation can be quantified directly using velocity mapping or by comparing the ratio of the stroke volumes of the right and left ventricles.

3.4.2 Septal Defects

Pulmonary valve stenosis and atrial septal defect are the commonest congenital deformities of the heart, but they may not prove to be significant until adolescence or early adult life when the gradients across the pulmonary valve become significant and can be measured from the jet velocity. The shunt across the septal defect can be measured by the volume method or by velocity mapping. It is important to determine the amount of blood shunting from the left (higher pressure side of the heart) to the right (lower pressure side). It is not uncommon for the shunt ratio to be as high as 4:1, with four times as much blood flowing through the lungs as the body. This shunt gradually and irreversibly damages the lungs, increasing their resistance to flow and eventually reversing the shunt and making closure of the defect irrelevant and dangerous. If only one

defect is present in the absence of valve regurgitation, the shunt can be measured by comparison of the outputs of the two sides of the heart. Velocity mapping measuring the shunt directly is more reliable.

4 FUNCTIONAL ASSESSMENT OF ACQUIRED HEART DISEASE

4.1 Traumatic Cardiovascular Disease

The commonest traumatic cardiovascular lesion due to road traffic and other accidents is a partial tear of the aorta causing a dissecting aneurysm. These can be detected with a computed tomography (CT) scan or an anatomical MR image which reveal the presence of the dissection. A dissection usually travels down the length of the aorta and sometimes it extends back towards the origin of the coronary arteries. Before any repair can be attempted it is essential to use velocity mapping to determine where the blood is flowing, and which branches to vital organs arise from the true lumen and which from the false lumen.¹⁵

Tears and penetrating injuries such as stab wounds to the heart and the associated blood in the pericardium can be seen on spin echo and better on gradient echo images. Blood flowing in and out of false aneurysms indicates their size, and more significantly, differentiates them from pericardial cysts.

4.2 Inflammatory and Toxic Damage to the Heart

4.2.1 Valve Disease

The mitral and aortic valves may be damaged by bacterial infection on an already damaged or abnormal valve, or by rheumatic fever which for the past decades has been uncommon in the western world. Hypersensitivity to *Streptococcus* spp. still commonly causes valve disease in developing countries and there is now a resurgence, notably in the USA. Thickened valve cusps can be seen on 'black blood' images or as filling defects on white blood images. However, life depends on the normal function of valves, and appearance may not correlate with the severity of their malfunction. Turbulent and regurgitant flow associated with stenosis and regurgitation due to rheumatic fever, etc. can be visualized as areas of signal loss on gradient echo images. If velocity mapping is not available, a remarkably accurate assessment of the volume of a regurgitant jet can be made from the proportion of the chamber occupied by the jet and the duration of the back flow.¹⁶ Stenosis and regurgitation are best measured directly using velocity mapping with short echo times. A TE of 3 ms to the second echo can capture velocities of up to 6 m s^{-1} ; the highest velocity attained through a stenotic valve. Multivalve disease invalidates comparison of stroke volumes from the two sides of the heart. The same multislice technique can be used to measure ventricular mass, which is increased in congenital cardiomyopathies.

4.2.2 Heart Muscle Disease

Heart muscle can be affected directly by viral illnesses such as influenza, the ME virus and glandular fever. Conditions such as post partum cardiomyopathy and inflammatory/allergic

infiltrative processes such as rheumatic fever also impair muscle function. Alcohol, drugs, and industrial toxic substances can also cause generalized dysfunction of the myocardium. In florid cases, cine NMR imaging is sufficient to demonstrate the dilated poorly contracting heart with a low ejection fraction. In less obvious cases, measurement of global ventricular function, as described below, is required.

4.3 Neoplastic Disease

Primary malignant tumors of the heart muscle are uncommon. They can be seen invading the muscle on multislice NMR images. Their effects on cardiac function can be determined by measuring global and regional function (see sections 4.4.2 and 4.4.3). Benign tumors and developmental cysts are commoner and do not usually have a significant effect on heart function, but repeated studies are necessary to check them for malignant change. Tumors in the atria can float through the atrioventricular valves during atrial systole and be blown back into the atria during ventricular systole, causing cardiac dysfunction by obstructing the valves and by displacing blood in a pumping chamber. Anatomical images do not distinguish well between intracardiac blood clot and intracavity tumor on spin echo images and gradient echo, and velocity mapping techniques are needed to reveal the presence of clot. Tumors in the right atrium may appear to have an obvious connection to the atrial wall but are frequently extensions of tumors in other parts of the vascular system which have grown along the great veins into the atrium. An 'NMR search' can locate the origin of the tumor. The hemodynamic significance of intracavity space-occupying lesions can be determined by velocity mapping. More frequently the heart is invaded by a local tumor such as a lung cancer with hilar glandular involvement. In these cases cardiac function can be impaired in three ways: by stiffening of the wall, by reduction of chamber size due to the mass of tumor tissue, or directly by tumor replacing contractile elements of the heart.

4.4 Degenerative Heart Disease

Most cardiovascular deaths, and hence about 40% of all deaths, are due to various forms of degenerative heart disease of which the commonest are hypertension and atherosclerotic disease.

4.4.1 Hypertension and Ventricular Mass

The reduction of ventricular mass following effective treatment of hypertension can be monitored using the multislice method (section 2.3). The muscle hypertrophy caused by high blood pressure can be quantified using the same multislice technique as for ventricular volumes.¹⁷

Studies of the caval or pulmonary venous flow which normally exhibit two similar flow peaks, one in systole and one in diastole, can be used to distinguish between ventricular function which is abnormal due to valvar regurgitation which causes an enhanced second peak 'constriction' of the heart by pericardial effusion or scar tissue around it. 'Restriction' due to stiffness of the heart itself, usually as a result of an inadequate blood supply due to coronary artery disease, correlates with an enlarged first peak.

Ventricular function can be studied globally or regionally.

4.4.2 Global Ventricular Function

Ventricular function measurements are clinically most relevant, but the heart has four chambers and the techniques described here are equally relevant to the atria. Global ventricular function measured in the resting state is frequently within normal limits, but the patient's disability indicates that there is inadequate cardiac output during exercise associated with normal activities.

Pharmacological stress (section 4.4.4) can reveal occult abnormalities of global function in two ways: by changes in velocity and acceleration of blood in the aorta, or by changes of stroke volume and ejection fraction.¹⁸

In the normal heart, increasing doses of a pharmacological stress (section 4.4.4) agent such as dobutamine cause an increase in aortic blood flow, velocity, and acceleration. In the abnormal heart, increasing the dose produces increased performance up to a much lower limit than in the normal heart, which has large reserves of power, and there is a 'fall off' in performance at dose levels which in the normal heart would still increase velocity. The dose level at which the 'fall off' occurs is an indication of the extent of the myocardial damage.

When the resting global function is at the lower end of normal limits, and pharmacological stress (section 4.4.4) indicates myocardial dysfunction with exercise, this may be because regions of the ventricle are contracting suboptimally, not contracting, or even moving paradoxically, bulging during systole thereby further disadvantaging the remaining normal heart muscle. In these cases it is necessary to study regional ventricular function.

4.4.3 Regional Ventricular Function

Multislice VLA, HLA, or, most usefully, SA views of the heart can be used to assess regional thickening and movement of the heart wall during contraction. If these appear normal but the clinical history suggests otherwise, then pharmacological stress is required.

The inner surface of the heart muscle is under maximum stress during cardiac contraction and is remote from the blood supply which enters the heart from its outer surface. The earliest sign that the heart is becoming injured is the failure of the subendocardial muscle fibers to 'actively relax' to enable filling at the beginning of diastole. Later in the disease process, contraction of these muscle fibers is also impaired. Velocity mapping of the inner surface of the heart in the direction of the long axis of the heart provides a sensitive measure of the elasticity and capability of the heart to fill actively. Later in the disease process, the same velocity mapping technique can be used as an accurate measure of the local failure of contraction.¹⁹

4.4.4 Pharmacological Stress

To mimic normal exercise, pharmacological stress using inotropic agents to increase cardiac work are used. Intravenous dobutamine, which has a half-life of less than 100 s, is an example of a safer, effective agent than the long-acting coronary vasodilator dipyridamole (Persantin), which is more

commonly used. Any angina caused by the dobutamine infusion passes off within 90 s of stopping the infusion.²⁰

Pharmacological stress agents highlight areas which fail to contract normally, and indicate which coronary artery territory is receiving an inadequate blood supply. During simulated exercise there is good correlation between areas which do not thicken and move during systole and bolus tracking of a 'pseudo blood pool' magnetic resonance contrast agent. Both correlate well with nuclear medicine techniques.²¹

Measurements such as global and regional ventricular function demonstrate the effect, rather than the cause, of reduced ventricular function, which is most commonly a result of a diminished blood supply caused by atheromatous disease partially blocking the coronary arteries.

4.5 Atheromatous Disease

Atheromatous disease is progressive, and from demographic studies and animal experimentation is known to be reversible in its early presymptomatic stages (see section 8). The reader, hopefully a normal subject, requires answers to three fundamental questions about atheromatous disease. (a) Have I *got* it? (b) Are the *atheromatous* plaques of a type which can ulcerate and cause sudden death? (c) Can MR monitor the *efficacy* of preventive and therapeutic measures? An NMR machine capable of chemical shift imaging and velocity mapping is capable of answering all these questions.

4.5.1 Arterial Compliance

(a) *Have I got arterial disease?*: Atheromatous disease, mainly in the coronary arteries in the male and the carotid arteries in the female, appears not to coexist with a normal compliant arterial system. For this reason, measurements of aortic compliance, or its reciprocal the velocity of the onset of the arterial pulse wave along the aorta, can be used as a screening test to determine whether the subject is normal or an arteriopath.²² Aortic compliance can be determined by NMR directly by measuring the volume of the arch of the aorta at peak systole when it is most dilated, and at the end of diastole when its elastic recoil reduces it to its smallest volume. It can be derived indirectly with similar accuracy by measuring the onset of the arterial pulse wave in the ascending aorta and at the end of the arch of the aorta during peak systolic flow. In a normal subject under the age of 55, the pulse wave takes an average of 32 ms to traverse the arch, whereas if the transit time of the leading edge of the pulse wave takes less than 12 ms diffuse arterial disease is present. This simple screening test divides subjects under the age of 55 into three groups: athletes who have remained fit; the average normal; and arteriopath. Over this age the normal age-related aortic dilatation and reduction of arterial compliance is such that all subjects appear to be arteriopath.

4.5.2 Chemical Shift Imaging

(b) *Are the atheromatous plaques of a type which can ulcerate and cause sudden death?*: If the patient is shown to be an arteriopath by the screening tests outlined above, arterial plaques in the larger vessels can be found on spin echo images of the vessel walls (Figure 2). The presence of the plaque can be

confirmed and artefacts excluded by detecting acceleration of blood upstream of the obstruction, increased velocity across it, and deceleration downstream of it.

Water and fat images of the plaque can be acquired by using Dixon's selective reading of fat and water or Hinks' selective excitation of fat and water. A subtraction image indicates the percentage of lipid present.²³ Figures 3(a) and (b) show an atheromatous plaque with low lipid content. The range of lipid content in a plaque varies from zero up to a maximum of 28%. Figures 4(a) and (b) show a plaque with a high lipid content. A fibrous plaque [Figures 5(a) and (b)] with no or very low lipid content, though it impairs the circulation, is unlikely to cause sudden death. A plaque with a high lipid content puts the subject at risk because the plaque may rupture and ulcerate, precipitating acute thrombosis on its surface and, frequently, sudden death.

At the present stage of development, chemical shift imaging is only applicable to larger vessels, and the resolution is inadequate for NMR studies of coronary arteries based on single breathhold imaging acquiring 16 turbo-FLASH images. Furthermore, fat suppression techniques are needed in order to produce accurate images of the coronary arteries and velocity measurements in them, because phase changes due to the presence of fat surrounding the vessels invalidate the Dixon technique. Coronary velocity mapping is however adequate for the determination of the hemodynamic significance of coronary plaques by measuring the increased velocity across the plaque taking 24 heart beats (a breathhold duration within the capabilities of most subjects). The way ahead for coronary imaging depends on the development of velocity encoded echo planar and spiral imaging, both techniques with potentially sufficient resolution to enable analysis of coronary plaques. At present the inference has to be made that the lipid content of plaques in the coronary arteries is similar to that in plaques elsewhere in the circulation, as is usually the case.

Figure 2 Atheromatous plaques (P) in the aorta of a 59-year-old male seen on a black blood spin echo image

Figure 3 (a) A spin echo image of an atheromatous plaque (P) in a cadaveric specimen of aorta. (b) The image produced by subtraction of the fat and water images. There is no signal in the plaque which contains no lipid, confirmed by histology

4.5.3 Monitoring Atheroma using Functional NMR

(c) *Can NMR monitor the efficacy of preventive and therapeutic measures?*: Experiments with artificially induced atheroma in animals show that plaques regress with starvation (see section 8). Simple preventive measures including strict diet and exercise have also been shown to cause regression of atheromatous plaques. In subjects with very high cholesterol

Figure 4 (a) Spin echo cross-sectional images of a cadaveric specimen of human aorta with an atheromatous plaque (P) and a test tube with fat floating on water (W + F). (b) The images produced by subtraction of fat and water images. The plaque (P) and the periaortic fat have high signals corresponding with the high lipid content in the histology specimen. There is a line of high signal on the interface between the fat and water in the test tube (arrowed)

and other lipid levels, lipid-lowering agents may be necessary to augment the simple preventive regime. The advantages of NMR are that functional studies can be repeated regularly to monitor the progress of preventive measures.

Figure 5 (a) A spin echo image of the abdominal aorta in a 61-year-old male showing a typical asymmetric plaque (P). (b) The image produced by subtraction of fat and water images. The plaque (P) has a lower signal than the marrow (M) in the vertebral body which contains fat in a similar proportion to a lipid-rich plaque; therefore this is a fibrous plaque which will not rupture and cause sudden death

5 THE FUTURE

More versatile magnetic resonance machines capable of echo planar imaging and spiral velocity mapping will become available. These machines will use a new generation of open-access magnets in which ultrasound and laser intervention will

be done using direct NMR vision. Ultrasound surgery with NMR vision has the advantage that the ultrasound energy can be applied at a low level using the changes to the NMR signal with increased temperature to confirm that the ultrasound transducers are focused on the area of interest. The ultrasound energy can then be increased to ablate the lesion. The massive intellectual pool of knowledge of NMR will be switched from less common diseases to cardiology, oncology, and to the lung. Proper training in cardiovascular NMR is required, not so much for imagers, as for cardiologists and experts in vascular disease.

6 CONCLUSIONS

Functional NMR evaluation of the cardiovascular system using volume measurements, velocity encoded rapid imaging, and chemical shift imaging is capable of making the diagnosis in congenital and acquired cardiovascular disease which, between them, cause the largest number of deaths of any disease in the western world and massive morbidity and suffering. Furthermore, for the first time in the history of medicine, there is the opportunity to apply preventive measures to eradicate the epidemic of preventable arterial disease.

8 BACKGROUND NOTE

Atheromatous disease was unknown in Central Europe after World War I. Autopsy studies at the London Hospital from 1908–40 showed a steady increase in coronary artery disease. Casualties in the starving population of the siege of Leningrad in World War II showed no arterial disease; likewise there was no atheromatous disease in the survivors of concentration camps. Young soldiers killed in the Korean and Vietnam Wars showed massive diffuse disease. Experimental atheroma in laboratory animals regresses with starvation. Atheromatous disease does not coexist with wasting diseases. It also varies not only from time to time but from place to place. There are wide variations in its incidence in apparently genetically similar populations in different countries. There is no relationship between the 'spend' on health care and the incidence of disease. The USA spends the highest proportion of its GDP on health care and the UK nearly the lowest. Both countries are amongst those with the highest incidence. France, a high spender, and Japan, the lowest, share the lowest incidence of occlusive vascular disease.

Coronary Artery Disease Evaluated by MRI

Robert R. Edelman and Warren J. Manning

Beth Israel Hospital, Boston, MA, USA

Magnetic resonance imaging has had a profound clinical impact in several areas, including the brain, spine, and joints. A variety of technical advances have expanded the applications of MRI into areas where motion can be problematic, such as the abdomen. Fast imaging techniques also permit good quality images of the heart to be acquired, either for the demonstration of anatomy or for the measurement of function. Nonetheless, the clinical impact of MRI in the heart has only been modest. Aside from the technical challenges involved in imaging the beating heart, alternative, less expensive, and more readily available imaging modalities, such as ultrasound and radionuclide scintigraphy, can usually provide the desired information.

There is one area where alternative noninvasive imaging tests fall short, i.e. in the assessment of myocardial ischemia. Cardiovascular disease remains the leading cause of death in the United States with an estimated 1.2 million myocardial infarctions and 600 000 deaths per year attributed to coronary artery disease.¹ Minimally invasive tests for myocardial ischemia include single photon emission tomography (SPECT)^{2,3} and positron emission tomography (PET).^{4,5} These tests reveal perfusion abnormalities, but do not depict the coronary artery stenoses that cause them nor do they provide direct measurements of coronary artery blood flow. Transthoracic and transesophageal echocardiography can depict portions of the coronary arteries, but not sufficiently for routine clinical use.^{6–8} While transesophageal echocardiography does not require contrast injection, it does require esophageal intubation and has associated risks of death, esophageal perforation/laceration, aspiration/hypoxia, and arrhythmias.⁹

The 'gold standard' for the evaluation of the coronary arteries is contrast angiography with over 500 000 diagnostic cardiac catheterizations performed annually in the United States. Despite the development of multiple noninvasive tests for the detection of myocardial ischemia, up to 20% of these coronary angiograms reveal insignificant coronary artery disease.¹⁰ Information derived from such angiograms, however, is the standard by which mechanical interventions and many medical therapies are planned. In addition, prognostic information is also gained from data regarding coronary artery patency.

Hospital charges alone for cardiac catheterizations have been estimated at over \$1.8 billion annually. In addition, coronary angiography carries with it a low, though finite major complication rate—death (0.12–0.20%), cerebrovascular accident (0.03–0.20%), myocardial infarction (0.0–0.25%) and a

minor complication rate—vascular complication, local infection (0.57–1.6%), or arrhythmias (0.30–0.63%).^{11–13} The high cost and associated risk make routine coronary angiography inappropriate for use as a screening test. Furthermore, while semiquantitative techniques exist for estimating the flow restriction caused by a coronary artery stenosis based on the conventional angiogram,¹⁴ they do not provide a quantitative measure of coronary artery blood flow.

Magnetic resonance (MR) imaging is well suited for evaluating the heart, with excellent soft-tissue contrast and the ability to image the heart in double-oblique tomographic sections. Complex cardiac anatomy¹⁵ and systolic function¹⁶ have already been elucidated using MR imaging techniques. Magnetic resonance angiography is currently being used in several clinical applications, including screening for intracranial aneurysms,¹⁷ detection of stenoses of the extracranial carotid arteries,¹⁸ vertebro-basilar system, and renal arteries.¹⁹ If the techniques of MR angiography could be extended successfully to the heart, then MR might be used to predetermine which patients should go on for coronary catheterization, to follow high-risk patients noninvasively, to quantify flow reserve so as to determine the physiological significance of a stenosis, or ultimately as a cost-effective substitute for catheterization.

Human coronary arteries are small in caliber. The left main coronary artery is typically 4–6 mm in diameter²⁰ while the left anterior descending and left circumflex coronary arteries are generally 3–4 mm at their origins and taper distally. The right coronary artery supplying less myocardium is smaller than the left main, and is typically 3–4 mm proximally. High-resolution MR angiography of arteries of similar caliber (e.g. circle of Willis) to epicardial coronary vessels has been successful, but reproducible coronary angiography has remained elusive due to the effects of significant cardiac and respiratory motion. Standard ECG-gated spin echo and gradient echo cine images only occasionally show portions of the coronary arteries, and these images are not adequate for detailed evaluation.²¹

There are several fast imaging methods that have been used for coronary artery imaging. Three-dimensional gradient echo methods²² permit thin sections and short *TE*, thereby minimizing partial volume averaging and flow-related dephasing. With 3D approaches, however, saturation effects are more severe than with 2D approaches, resulting in suboptimal flow contrast particularly in the setting of low flow velocities. Unfortunately, long scan time for 3D acquisitions (at least several minutes for ECG-gated studies) precludes breath-holding, so that significant blurring from respiratory motion will occur.

Subtraction methods also have potential value for coronary artery imaging. One approach involves the interleaved acquisition of a pair of projection (thick section) images, of which one has a spatially localized inversion pulse applied to the aortic root to tag the coronary inflow.²³ Since only the signal intensity of the coronary arteries is altered by the inversion pulse, background and cardiac chamber signals are eliminated by image subtraction. Potential drawbacks of this method are the need for prolonged breath-holding periods (e.g. 24 s or longer), inadvertent saturation of other structures such as blood within the left atrium, dependence of flow contrast on the R–R interval, and potential misregistration resulting in imperfect subtraction. The method also assumes that blood within the major epicardial coronary arteries is completely displaced

within one R–R interval by blood from the aortic root. The use of a thick section also has the drawback of increased intravoxel dephasing compared with the use of thin sections. Nonetheless, encouraging preliminary results have been demonstrated in healthy volunteers.

Conventional gradient echo pulse sequences used for cine cardiac imaging consist of a radiofrequency pulse followed by a gradient refocused echo. The data acquisition is synchronized to the cardiac cycle. One line of data (one phase-encoding step) is acquired for each phase of the cardiac cycle within one R–R interval. As a result, the time required to acquire 128 lines of data (the amount required for a 128×256 matrix image) is $128 \times \text{R–R interval}$. For a 1-s interval, the imaging time is approximately 2 min, too long for a breath-hold. In order to acquire the images within a breath-hold interval, the sequence is modified so that up to 10 lines of data are acquired in rapid sequence within a 100 ms time period.²⁴ This group of lines is called one segment, and the imaging technique is called *segmented turboflash* or *breath-hold cine*. In our experience, there is relatively little blurring of coronary artery detail for segment durations up to 100 ms, but the blurring worsens as the duration is further increased. Imaging is performed during diastole, when cardiac motion is least and coronary flow velocities are high. One segment is acquired during each heart

beat, and a series of these segments, acquired over multiple heart beats, are then combined to create a whole image. For instance, 16 segments, each consisting of eight lines of data, would be combined so as to complete a 128×256 matrix. The imaging time would be 16 heart beats, on the order of 16 s or less. Cine imaging is also feasible by acquiring segments in rapid sequence (one segment per cardiac phase) within each breath-hold.

Flow velocities in the coronary arteries of resting subjects are rather low, on the order of $10\text{--}30\text{ cm s}^{-1}$. As a result, it is difficult to develop adequate flow contrast in the coronaries, compared to the adjoining myocardium, on the basis of inflow effects alone. This is a particular problem when the coronary arteries are imaged longitudinally. However, the epicardial portions of the coronary arteries are typically surrounded by fat. It is possible to apply fat suppression pulses (binomial or chemical shift selective) to diminish the signal intensity of the epicardial fat. By combining the segmented turboflash method with fat suppression techniques, the proximal and more distal portions of the epicardial coronary arteries are routinely depicted.

We have begun clinical studies of MR coronary angiography (Figure 1 and 2).²⁵ Sensitivity and specificity for coronary artery disease are in the 80–90% range, which is comparable with thallium scintigraphy. One problem has been poor flow contrast resulting from slow flow distal to a severe stenosis, making it difficult to distinguish a stenosis from an

Figure 1 Left anterior descending coronary artery. (a) Axial segmented turboFLASH image shows the left anterior descending coronary artery (arrow) and a septal branch. (b) Oblique view in another subject shows the left anterior descending coronary artery (arrow) and a septal branch

Figure 2 Severe stenosis of the right coronary artery. (a) MR angiogram shows the lesion (arrow). (b) Coronary catheterization

occlusion. This problem might be ameliorated by the use of contrast agents. Blood pool contrast agents are currently under development that could greatly improve the quality of coronary artery images.

Compared with our original technique, we have recently obtained a greater than 50% improvement in signal-to-noise ratio by lowering the sampling bandwidth of the sequence from 195 Hz pixel⁻¹ to 78 Hz pixel⁻¹, keeping the echo time at 7 ms. This was possible because of enhancements in the gradient capabilities of our MRI system. The signal-to-noise ratio improvement has allowed us to position the patient supine within the body coil, which is better tolerated than the prone positioning previously required with a flat surface coil. Further 2–3-fold signal-to-noise improvements will be possible with the introduction of circularly polarized whole-volume phased-array coils.

Flow velocity measurements can be done by using a phase contrast modification of segmented turboFLASH, in which two segmented turboFLASH images are acquired in a single breath-hold.²⁶ In one sequence, the slice-selective gradient incorporates a three-lobed, velocity-compensated waveform that is insensitive to flow; in the other, a bilobed waveform is applied resulting in a measurable shift in the phase of the MR signal of flowing blood. The gradients were calibrated to permit flow velocity measurements up to 150 cm s⁻¹. A 96 × 256 acquisition matrix is used with pixel dimensions of 1.4 mm × 0.8 mm. Four images are produced by this sequence, comprising magnitude and phase reconstructions of the flow-insensitive and flow-sensitive data. The flow-insensitive magnitude image shows vessel anatomy, whereas subtraction of the flow-insensitive and flow-sensitive phase images produces a phase difference image in which the phase shift is proportional to the flow velocity along the direction of slice selection. Image subtraction eliminates background phase shifts unrelated to blood flow.

The method was tested in 12 subjects studied at rest and four studied before and during pharmacologic stress using intravenous adenosine. Flow velocities at rest in the midportion of the right coronary artery were 9.9 ± 3.5 cm s⁻¹ (*n* = 12); in the proximal left anterior descending artery they were significantly higher, measuring 20.5 ± 5.2 cm s⁻¹ (*n* = 6). With adenosine, flow velocities typically increased at least fourfold. These results indicate that noninvasive measurement of coronary artery flow velocities is feasible using MR angiography. Table 1 summarizes the current performance of MR coronary angiography in our clinical practice.

Finally, entirely new imaging techniques are likely to be developed that are advantageous compared with segmented turboFLASH. The fastest known method for creating an MR image is called echo planar imaging (EPI).²⁷ The most commonly used EPI method, called blipped EPI, oscillates the read-out gradient so that a series of gradient echoes are generated. Each gradient echo is separately phase-encoded by a short duration gradient pulse (the blip); alternatively, a constant amplitude phase-encoding gradient can be applied for the entire read-out period. Using specially designed gradient coils, EPI can generate a series of 64 echoes in as little as 32 ms. Thus a 64 × 128 matrix image can be acquired in 1/30th of a second, which is sufficiently short to freeze any kind of physiologic motion, including that of the heart. We have had promising results imaging the coronary arteries recently using an echo planar MR angiography method that circumvents

Heart: Clinical Applications of MRI

Scott D. Flamm and Charles B. Higgins

University of California at San Francisco, San Francisco, CA, USA

1 INTRODUCTION

The first electrocardiographically gated magnetic resonance images of the human heart were shown in 1984. In the decade that followed several important techniques have been developed which facilitate the use of MRI for the evaluation of cardiovascular morphology, contractile function, myocardial tissue characterization, and blood flow. With these techniques, MRI has been found to be effective for the investigation of a variety of acquired and congenital cardiovascular diseases. This role of MRI in relation to preexisting cardiac imaging techniques continues to evolve.

The clearly defined indications for the effective use of MRI in acquired heart disease include the evaluation of pericardial disease, right ventricular dysplasia, thoracic aortic disease, intra- and extracardiac masses, cardiomyopathies, valvular heart disease, ischemic myocardial disease, and the morphology of the coronary arteries.

The indications for the application of MRI in congenital heart disease include the assessment of pulmonary artery morphology, coarctation of the aorta, vascular rings, complex congenital heart disease, and postoperative evaluation.

2 IMAGING TECHNIQUES

A multitude of sequences are available for cardiac imaging (Table 1). These include spin echo and multiplanar multiphasic techniques for morphological information of both cardiac and

extracardiac structures (e.g. the great vessels). Anatomical information also can be obtained using electrocardiogram (ECG)-gated cine gradient echo (cine GRE) and newer, fast gradient echo techniques that sample segmented k -space during a single breath-hold (breath-hold cine GRE). These latter two techniques are also useful for acquiring multiple, ECG referenced images of the heart, in either long or short axis projections similar to echocardiography, which may be electronically 'looped' and viewed in a cinematic format to evaluate global ventricular function and segmental wall motion. Velocity-encoded cine MRI techniques can assess quantitatively blood flow velocity and flow volume within the heart to evaluate intracardiac shunts, and valvular pathology and function. This same technique may also be used in the great vessels to determine pulmonary and aortic blood flow, including differential flow to the right and left pulmonary arteries, as well as to estimate gradients across areas of stenosis such as in coarctation of the aorta.

For multislice spin echo MRI, ECG gating is required to 'freeze' the motion of the heart, and respiratory compensation further improves image quality (see also *Cardiac Gating Practice* and *Motion Artifacts: Mechanism and Control*). In adults, typical sequences include ECG gating T_1 -weighted images of 7–10 mm slice thickness obtained in the axial plane, with supplemental images acquired in the sagittal, and oblique sagittal, axial, and coronal planes, as dictated by the particular clinical concern.

In adults and children, body coils are used most commonly. Flexible phased array surface coils are gaining in use for both general and special purposes, as they provide greater resolution and image contrast as a result of improved signal-to-noise ratios. For some infants and small children a head coil may be practical, and will result in the greatest resolution and signal-to-noise ratio for the relatively small areas of interest.¹

3 LEVEL OF CURRENT CLINICAL ACTIVITY

Cardiovascular MRI is used primarily for detection and delineation of anatomical abnormalities according to a recent survey of members of the Society for Magnetic Resonance

Table 1 Techniques for MRI of the Heart

Technique	Application
ECG-gated spin echo	Anatomy and morphology
Cine GRE	Anatomy; atrial and ventricular dimensions and volumes; global and regional ventricular function
Fast (turbo) GRE	Anatomy; myocardial perfusion; rapid imaging of great vessels
Breath-hold, segmented k -space GRE	Anatomy including coronary arteries; myocardial perfusion; global and regional ventricular function
Velocity encoded cine MRI	Valvular function (quantification of regurgitation, and estimation of peak valvular gradient), measurement of stroke volume and cardiac output of each ventricle, quantification of shunts, measurements of differential flow in right and left pulmonary arteries, quantification of gradients at stenoses of the pulmonary arteries or coarctation of the aorta
Echo planar	Global and regional function of left and right ventricles, quantification of regional myocardial blood volume and perfusion

Imaging. Of the responding centers, 46% reported exclusively clinical work, 3% exclusively research, and 51% both clinical and research. The majority of MRI studies are performed in the evaluation of thoracic aortic disease, congenital heart disease, and cardiac masses. While most studies are performed for morphological information, half of the centers also accomplish functional studies, usually for ventricular and/or valvular function, in conjunction with anatomical studies.²

4 ACQUIRED HEART DISEASE

4.1 Pericardial Disease

Differentiating constrictive pericarditis from restrictive pericarditis is the most frequent indication for applying MRI in pericardial disease. This is an important distinction because both diseases cause similar hemodynamic abnormalities, and are usually indistinguishable on cardiac catheterization. Only constrictive pericarditis can be alleviated by surgery. Constrictive pericarditis is seen most commonly after cardiothoracic surgery, and radiation therapy. On spin echo sequences it is manifested by local or generalized thickening of the pericardium to 4 mm or greater. This thickening is more readily evident over the right ventricle and right atrium. Associated findings include enlargement of the right atrium, inferior vena cava and hepatic veins, pericardial effusion, and tubular narrowing of the right ventricle. The reported diagnostic accuracy of MRI in establishing the diagnosis is 93%.³

MRI also can be used to examine the pericardium and its contents for evidence of effusion or hemorrhage, and mass lesions. Echocardiography is a fast, effective technique to determine the presence and general quantity of pericardial effusions, but can be less accurate in discerning hemorrhagic from nonhemorrhagic effusion, or determining the extent and location of loculated effusions, particularly in the posterior and basal portions of the heart. Spin echo MRI can easily determine the anatomical location and size of effusions, as well as the extent of loculations in all portions of the heart. It also has the advantage of more easily identifying the presence of pericardial masses, which may represent metastatic tumors responsible for hemorrhagic and/or recurrent effusion. The hemorrhagic nature of effusions can be identified with T_1 -weighted spin echo sequences as high signal intensity, in contrast to the very low signal intensity of nonhemorrhagic pericardial effusions.

4.2 Right Ventricular Dysplasia

Right ventricular dysplasia is a relatively uncommon disorder generally occurring in young people, and manifesting as potentially life threatening arrhythmias originating from the right ventricle. The diagnosis is predicated on the identification of fatty infiltration or fibrosis replacing the right ventricular myocardium. The diagnosis of right ventricular dysplasia is difficult to establish even with electrophysiological studies and myocardial biopsy.

The primary diagnostic feature on MRI is transmural fat within the free wall of the right ventricle, but the spectrum of

findings includes 'islands' of fat within, or abnormal thinning of, the right ventricular free wall, regional or global contraction abnormalities of the right ventricle, and aneurysmal outpouching of the right ventricular outflow tract during systole.⁴ Axial spin echo images focused on the right ventricular free wall are used to demonstrate myocardial fat, and cine GRE sequences obtained in the axial or horizontal long axis are useful to evaluate regional right ventricular contraction abnormalities. The utility of MRI in establishing the diagnosis noninvasively was recently documented in a group of patients with biopsy proven right ventricular dysplasia. Those patients with inducible right ventricular arrhythmias were significantly more likely to have identifiable fat within the myocardium, contraction abnormalities of the right ventricle, and/or a lower ejection fraction.⁵

The course of patients with right ventricular dysplasia typically has been followed with periodic right heart angiography and myocardial biopsy, which entails a significant degree of risk. MRI appears to be an effective technique for identifying at least a subset of patients with right ventricular dysplasia, and may become the procedure of choice for follow-up.

4.3 Thoracic Aortic Disease

Aneurysm and dissection are the most common indications for MRI of the thoracic aorta. Spin echo sequences are used to demonstrate the morphology of thoracic aortic aneurysms, which may occur as a result of atherosclerosis, trauma, or Marfan's syndrome, or may be mycotic or syphilitic in origin. In aortic dissection the intimal flap can often be identified on spin echo images, but is more readily seen with GRE and cine GRE sequences (Figure 1). These techniques also are effective in correctly identifying the true and false lumens, and differentiating slow flow versus thrombus within the false lumen. Additionally, MRI can identify the presence of hematoma within the wall of the aorta.⁶ This cannot be defined with X-ray angiography.

MRI is a highly sensitive and specific technique for the detection of aortic dissection that can identify both the intra- and extravascular space, and the walls of the aorta. Conventional angiography has been considered the gold standard, but requires an invasive procedure, may incompletely identify the false lumen and its extent, and is unable to evaluate fully the walls of the aorta, and the extravascular space. MRI has proven to be superior to X-ray angiography and transthoracic echocardiography.

MRI has been compared to transesophageal echocardiography, which is also a highly sensitive technique, and has the advantage of being portable, permitting its use in critical and unstable patients unable to leave the intensive care setting. Multiple studies have demonstrated a similar high sensitivity (98–100%) for both methods, but MRI has a significantly higher specificity (98–100%) than transesophageal echocardiography (68–77%) in high risk populations.^{7,8}

Evaluation of the thoracic aorta usually requires approximately 20–30 min using standard cine GRE sequences. Newer sequences, particularly segmented k -space breath-hold cine GRE sequences, can acquire each slice in 12–16 s, providing images of the entire thoracic aorta in approximately 5 min. The study can be extended to the abdominal aorta to evaluate for potential involvement of the mesenteric vessels with the addition of a few minutes of imaging time.

Figure 1 Series of selected images from a patient with a type A aortic dissection involving the aortic arch, descending thoracic aorta, and abdominal aorta. These are images acquired using a breath-hold segmented *k*-space cine MRI sequence acquired at the level of (a) the aortic arch, (b) the left pulmonary artery, (c) the main and right pulmonary artery, and (d) the upper abdomen. Note the compression of the true lumen by the false lumen. The bright signal within the false lumen confirms the presence of flow. T, true lumen; F, false lumen

4.4 Intracardiac Masses

Tumor, thrombus, and valvular vegetations (as occur in bacterial endocarditis) are the primary considerations when there is concern for an intracardiac mass. There are no studies demonstrating the benefit of MRI for valvular vegetations; echocardiography remains the most effective noninvasive technique for this determination.

MRI is effective for evaluating intracardiac masses, and in most instances can differentiate between tumor and thrombus.⁹ Spin echo sequences are usually adequate to identify the size and location of intracardiac masses. Both tumors and thrombus tend to be isointense to myocardium on spin echo images; however, some thrombi may have a low signal intensity and be indistinguishable from the ventricular cavity without the additional application of cine GRE sequences.¹⁰ Cine GRE sequences are particularly useful in that they permit identification of the majority of masses, and typically are successful in differentiating thrombus from tumor.¹¹ The most common tumors include myxomas (usually left atrial), rhabdomyomas (usually right ventricular), and metastases from primary carcinoma of the breast or lung, or melanoma. On cine GRE images tumors tend to be intermediate in signal intensity, with

myocardium being low–intermediate in intensity, while thrombus is frequently very low in signal intensity. In the case of relatively fresh thrombus, high signal intensity may be present on cine GRE images. These signal characteristics hold true in the majority of instances; however, some tumors, particularly myxomas which have bled internally, may contain increased amounts of hemosiderin, making them very low signal intensity on GRE images.

4.5 Cardiomyopathy

There are four recognized types of cardiomyopathy—hypertrophic, congestive (or dilated), restrictive, and obliterative—each of which has a distinct constellation of morphological and functional features. The etiology of the myocardial abnormality is varied. Most forms are idiopathic in nature, but chronic injury from ischemia or toxins, or infiltrative disorders are responsible for a minority of cases. The hypertrophic and congestive forms have been studied extensively with MRI; less is known about the obliterative form as it is very rare, and encountered primarily in Africa.

Hypertrophic cardiomyopathy usually manifests as global hypertrophy of the left ventricular myocardium, though many

variants have been documented with MRI, including focal or diffuse septal hypertrophy, and midventricular and apical forms.¹² Cine GRE, acquired in either the long or short axis, has been used to quantify left ventricular mass, volumes, and ejection fraction in this disease. MRI has shown high accuracy and interstudy reproducibility for quantifying left ventricular volumes and mass, providing a precise technique for serial assessment during treatment.^{13,14} Patients with hypertrophic cardiomyopathy also demonstrate abnormal diastolic and systolic function. The overall heart size remains normal, but the end-diastolic volume and filling rates are reduced in both the left and right ventricles.¹⁵ Systolic function is hyperdynamic, and near obliteration of the ventricular cavity, particularly at the apex, is a characteristic feature (Figure 2).

In congestive cardiomyopathy the overall cardiac dimensions are increased, and there is left ventricular dilation. The

idiopathic forms have normal myocardial thickness, and as a result the myocardial mass is greater than normal. In patients with chronic injury or ischemic etiology the myocardium may be globally or focally thinned. As in the hypertrophic form, cine MRI in congestive cardiomyopathy can quantify the ventricular volumes and mass, and assess ventricular function and wall stress.¹⁶ Recent studies have demonstrated the effectiveness of using serial MRI examinations to follow patients with congestive cardiomyopathy undergoing treatment with angiotensin-converting enzyme inhibitor therapy.^{17,18}

Restrictive cardiomyopathy may have either normal or thickened myocardium, and normal, increased, or decreased left ventricular end-diastolic volume. The salient characteristic functional feature is markedly reduced diastolic compliance, which is similar to that seen in constrictive pericarditis. Constrictive pericarditis, however, may be differentiated by the

Figure 2 Short axis images of the heart in a patient with hypertrophic cardiomyopathy. The upper row of images were acquired in diastole (the images on the left are from near the apex, and the images on the right from the mid-ventricular region), and directly below each is the respective systolic image, demonstrating marked, global thickening of the left ventricular myocardium, and obliteration of the apical cavity during systole. The sequence used is a breath-hold segmented *k*-space cine MRI

abnormally thickened pericardium (>4 mm), usually noted over the right side of the heart. Patients who have restrictive cardiomyopathy with thickened myocardium (such as in amyloidosis) may be differentiated from those with hypertrophic cardiomyopathy based on the reduced systolic function in the former, compared with the hyperdynamic function in the latter.¹⁹

4.6 Valvular Heart Disease

MRI using cine GRE sequences can identify the severity, extent, and direction of the turbulent jet of blood across stenoses of the aortic, pulmonic, mitral, and tricuspid valves. Turbulence, on cine GRE images is shown as a signal void against the background of bright signal intensity blood in the great vessels or ventricle. Using these images as a reference, the peak velocity of the turbulent jet may be determined with velocity-encoded cine MRI images obtained perpendicular to the long axis of the turbulent jet near the valve's orifice. Velocity-encoded cine MRI can determine the peak velocity of stenotic jets with accuracy up to 6 m s^{-1} .²⁰ By using the modified Bernoulli equation [$\text{gradient (mmHg)} = 4 \times (\text{peak velocity (m s}^{-1})^2$)], the peak gradient across the stenosis can be calculated; this is one of the important clinical indicators used in determining the effectiveness of medical therapy, and, when necessary, timing of valve replacement surgery. Recent work has demonstrated the usefulness of this technique in both the aortic²¹ and mitral²² valves.

Cine GRE sequences also have been used to measure the extent and direction of the regurgitant jet in aortic and mitral insufficiency. Quantification of the volume of regurgitant flow may be acquired using velocity-encoded cine MRI sequences where the cardiac cycle (each R-R interval) is divided into 16 phases, and flow is measured at each phase of the cycle. In the case of aortic regurgitation, an imaging slice is acquired perpendicular to the long axis of the aorta proximal to the origin of the innominate artery. The data at each of the 16 phases can be plotted versus time, and the forward, reverse, and total flow calculated.²³ This method has the advantage of determining absolute flow, and has high interstudy reproducibility.²⁴ Regurgitant volume across the mitral valve has been calculated by measuring the amount of left ventricular inflow during diastole (velocity-encoded cine MRI slice across the mitral valve) and subtracting the left ventricular outflow during systole (imaging slice in the ascending aorta).²⁵

4.7 Ischemic Heart Disease

MRI has the potential to become an important technique to differentiate normal from ischemic or infarcted myocardium by combining information about morphology, function, and perfusion in a single study. Of these three the largest hurdle has been determining global and regional myocardial perfusion in a rapid, reproducible manner under conditions reflecting both the basal state, and stress.

The earliest attempts at differentiating ischemic from normal myocardium focused on acute infarctions because of the edema that occurs secondary to vascular leak at the site of damage. Increased water in tissue results in increased signal on T_2 -weighted scans in areas of acute infarction due to T_2 prolongation.²⁶ Subsequently, MRI contrast agents have been used to improve the distinction between acute and subacute infarc-

tions, and normal myocardium. Contrast enhancement (greater than the adjacent normal myocardium) has been noted uniformly in many reperfused areas of myocardium, or only peripherally in areas of infarction in which the central zones had necrosis, hemorrhage, or marked edema that limited or ceased blood flow centrally.^{27,28}

Detecting areas of stress induced ischemic myocardium has been approached using contrast-prepared fast imaging techniques. Recent studies have demonstrated the feasibility of monitoring the passage of a bolus of MRI contrast agent through the myocardium using rapid, sequential images.²⁹⁻³² Myocardium supplied by coronary arteries with angiographically proven significant stenoses demonstrates lower peak signal intensity after contrast administration, and a lower rate of signal increase than normal myocardium.²⁹ Ischemic myocardium, induced with the administration of dipyridamole, a pharmacological stress agent, also demonstrates lower peak signal intensity as compared with normal myocardium.³⁰ At present, imaging is limited to a few imaging planes for each study, but with the development of echo planar imaging, dynamic acquisition of the entire heart during the first pass of MRI contrast media will be feasible (see Figure 3; also *Echo-Planar Imaging*).

Ischemic myocardium also may be identified by functional wall motion abnormalities observed on cine GRE sequences acquired in the basal state or during pharmacological stress. Areas of threatened myocardium demonstrate decreased contractility during dipyridamole infusion.³³ One study found the sensitivity/specificity (percent values) for localization of stenotic vessels at 78/100 for the left anterior descending, 73/100 for the left circumflex, and 88/87 for the right coronary artery.³⁴ This technique has also been compared to radionuclide scanning using ^{99m}Tc -methoxyisobutyl isonitrile SPECT (MIBI SPECT), with no significant differences detected in sensitivity for lesion localization.³⁵ Dobutamine is another pharmacological stressor that has been used to assess wall motion abnormalities with cine GRE sequences. Dobutamine MRI studies have demonstrated close agreement with findings on dobutamine thallium-201 SPECT,³⁶ and a sensitivity and specificity of 81 and 100%, respectively, using coronary arteriography as the gold standard.³⁷

4.8 Coronary Arteries

MRA techniques have recently been used for imaging of the coronary arteries.³⁸⁻⁴⁰ The coronary arteries present a formidable challenge for MRI, because they are small structures whose motion within the thorax is complex, being influenced by the spiral contraction of the heart, expansion of the chest, and descent of the diaphragm.

The proximal and midportions of the coronary arteries have been demonstrated by MRA with a fat-suppressed, cine GRE technique using segmented k -space and breath-holding. In a group of 19 normal volunteers, and six patients with recent angiograms, the left anterior descending and right coronary arteries were identified in 100%, the left main in 96%, and the left circumflex in 76%.⁴¹ A subsequent study using a similar MRA technique in 39 patients with angiographically identified coronary stenoses demonstrated a sensitivity and specificity of 90 and 92% for detection of significant ($\geq 50\%$ narrowing) lesions.⁴²

Figure 3 Series of short axis images of the heart acquired repetitively at the same level over a 90 s period during bolus administration of contrast media. The transit of contrast material increases signal intensity first in the right ventricular blood pool, then left ventricular blood pool, and finally the myocardium of the right and left ventricles. The patient has had an infarction in the anterior and anteroseptal distribution (arrowheads); note the delayed rise in signal intensity compared to the adjacent normal myocardium

The use of complex, oblique planes has permitted visualization of more than 8 cm lengths of the right coronary artery and left anterior descending coronary artery (Figure 4).³⁸ Other recent advances include non-breath-hold three-dimensional

imaging using fat saturation and magnetization transfer contrast techniques. Initial work has demonstrated the first 3–10 cm of the left and right coronary arteries from a single 7–10 min acquisition.⁴³ Further improvements in scanning time, image

Figure 4 MRA of the coronary arteries using a breath-hold segmented *k*-space cine sequence. (a) An oblique coronal image demonstrating the proximal and midportions of the right coronary artery (arrowheads). (b) An axial image showing the left main and proximal left anterior descending coronary arteries (arrowheads)

resolution, and surface coil technology may result in a complete magnetic resonance angiogram of the coronary arteries.

5 CONGENITAL HEART DISEASE

5.1 Coarctation of the Aorta

MRI can provide excellent anatomic visualization of the aorta. Images are acquired first in the axial plane using a spin echo sequence, and then using these images as a reference a set of oblique sagittal images are acquired parallel to the plane of, and including, the ascending and descending aorta. These two sets of images can adequately describe the anatomical location and severity of the stenosis, including involvement of arch vessels, and degree of poststenotic dilation. A cine GRE sequence in the same oblique sagittal plane can demonstrate the jet of turbulent flow along the descending thoracic aorta just distal to the site of coarctation.⁴⁴ The gradient across the stenosis can be estimated from the peak velocity (using the modified Bernoulli equation described previously); measurements performed with velocity-encoded cine MRI reveal a close correlation ($r = 0.95$) with values obtained by continuous wave Doppler ultrasound.⁴⁵ The length of the turbulent jet has been correlated with the severity of stenosis, a factor important in gauging the appropriate timing of initial corrective surgical procedure, or subsequent repair in recoarctation.

At present, determining the optimal time for corrective surgery has been based on a combination of clinical findings and the echocardiographically determined gradient across the coarctation, both of which are only loosely correlated with the severity of stenosis. Recent work has revealed a unique ability of MRI in the evaluation of coarctation of the aorta. Velocity-encoded cine MRI was used to measure blood flow in the descending thoracic aorta just distal to the coarctation and at the level of the diaphragm, with the difference in flow representing the contribution from collateral vessels (Figure 5). While normal individuals have an average 8% decrease in blood flow along the descending thoracic aorta, patients with significant coarctations have an average 80% increase in flow.⁴⁶ This technique represents the only currently available noninvasive method to measure the extent of collateral development, and their contribution in supplying blood to the abdominal aorta.

5.2 Pulmonary Arteries

The evaluation of pulmonary arterial anatomy, orientation, size, and flow is critical to the management of children with lesions affecting the pulmonary arteries such as tetralogy of Fallot, and pulmonary atresia and stenosis.⁴⁷

The pulmonary arteries are best visualized using 3–5 mm ECG-gated spin echo images in the axial plane, followed by oblique sagittal images through the pulmonary infundibulum, and/or right and left pulmonary arteries. MRI can define accurately the location and severity of narrowing in the right ventricular outflow tract and main pulmonary artery, as well as associated poststenotic dilation.^{48,49} In a series of 12 patients who had undergone the arterial switch operation MRI correctly identified

92% of the pulmonary artery stenoses, while echocardiography identified only 58%. Moreover, MRI was superior in identifying peripheral pulmonary stenoses, as echocardiography visualized only seven of the 17 peripheral stenoses seen by MRI.⁵⁰

Pulmonary atresia is identified by a fibrous and/or muscular band at the expected junction of the main pulmonary artery and the right ventricular outflow tract, on both axial and sagittal images. Determining the presence or absence of the main pulmonary artery and continuity of the right and left pulmonary arteries is crucial information for surgical planning. At least two studies, using angiography as the gold standard, have confirmed the ability of MRI to determine correctly the status of main, left and right pulmonary arteries, without the need for an invasive procedure.^{51,52}

Quantitative, physiological information regarding flow within the pulmonary arteries can be obtained using velocity-encoded cine MRI images. This technique can accurately quantify both total, and right and left lung differential blood flow,⁵³ and correlates well with radionuclide lung scanning for the evaluation of relative blood flow to the left and right lungs.⁵⁴ This information is useful for determining the severity of stenoses and their effect on total and differential pulmonary blood flow (Figure 6). In addition, it may prove particularly valuable in serially assessing flow at sites of stenosis after balloon valvuloplasty, or surgical repair.

5.3 Vascular Rings

MRI is ideal to define the aortic arch and great vessel relationships because of its multiplanar capabilities and ability to image the adjacent air-filled trachea and esophagus, both of which may be compressed by the vascular structures. Spin echo sequences are typically employed in the axial and sagittal planes to demonstrate the commonly encountered abnormalities which include double aortic arch, right aortic arch with mirror image branching, right aortic arch with aberrant left subclavian artery, left aortic arch with aberrant left subclavian artery, and pulmonary sling. The sagittal images often best demonstrate the compression on both the trachea and esophagus. Coronal images may provide further information regarding double aortic arches.

Imaging may also be performed using magnetic resonance angiography, with either time-of-flight or phase contrast techniques.^{55,56} Both techniques produce signal primarily from moving blood resulting in images that reflect the intravascular space, similar to conventional contrast angiograms, but without the need for contrast or an invasive procedure. These sequences have a further advantage in that the images may be reconstructed into a three-dimensional format, and viewed from any desired angle. Further postprocessing permits close examination of a particular area of interest for detailed analysis.

5.4 Complex Congenital Heart Disease

Complex congenital heart disease requires definition of the complicated anatomical relationships of the heart. MRI permits segmental analysis of complex congenital heart disease by providing tomograms encompassing the great vessels, heart, and infradiaphragmatic structures. Axial spin echo sequences are

Figure 5 Patient with coarctation of the aorta. (a, b) ECG-gated spin echo images acquired in the axial and oblique sagittal projections, respectively. (c, d) Magnitude and phase images, respectively, from a VEC sequence acquired at the level of the diaphragm. Regions-of-interest have been placed over the aorta. (e) A flow curve can be derived, and blood flow at that level calculated (as described in the text). Similar information is obtained from a slice positioned just distal to the site of coarctation. The difference in blood flow between the sites in the descending thoracic aorta is a direct measure of the contribution of collateral blood flow to the abdominal aorta. A, ascending aorta; D, descending aorta; arrow, coarctation

usually sufficient to define the anatomy, with sagittal, coronal, and oblique imaging planes used to further complement the anatomical information.

A segmental approach is used to define the anatomy beginning with determination of the abdominal situs, and the relationship of the inferior vena cava and aorta. After this, the

pattern of blood flow through the heart and great vessels is determined starting with the systemic and pulmonary venous connections, and then identifying the atrial situs, and presence and position of the atrioventricular valves. Next, the ventricular anatomy, and ventriculoarterial connections and great artery relationship are determined.

Figure 6 (a) Axial spin echo image of a patient with stenosis (between arrows) of the proximal right pulmonary artery. VEC MRI can be performed perpendicular to the main, and proximal right and left pulmonary arteries, and the total blood flow to the lungs, and differential blood flow to each lung calculated. (b) The different flows calculated for each of the respective arteries are demonstrated here. R, right pulmonary artery; L, left pulmonary artery; M, main pulmonary artery

The absolute and relative sizes of the ventricular system including quantification of ventricular mass, and the quantity and spatial extent of septal tissue are all well defined by MRI.⁵⁷⁻⁵⁹ Many complex lesions have been evaluated correctly with MRI including double-outlet right ventricle,^{60,61} double-outlet left ventricle,⁶² double-inlet ventricle,⁶³ single ventricle and atrioventricular canal,⁶⁴ partial and total anomalous pulmonary venous connection,^{65,66} and Ebstein's anomaly.⁶⁷ In a study of 29 patients with complex lesions, MRI was shown to be more informative for defining complex congenital heart disease than conventional angiography.⁶⁴ Receiver operating characteristic curves have been derived for MRI at a specificity level of 90%, demonstrating 100% sensitivity for evaluating great vessel relationships, ventricular septal defects, viscerotransposition, and ventricular loop, 95% for right ventricular outflow tract obstructions, 94% for thoracic aortic anomalies, and 91% for atrial septal defects.⁶⁸

5.5 Postoperative Evaluation

The metallic clips, wires, stents, shunts, and prosthetic valves used in interventional and surgical correction of congenital heart disease are sometimes problematic for MRI. On magnetic resonance images these devices may result in paramagnetic artifacts that degrade image quality, but fortunately, in most instances, they do not affect significantly the diagnostic utility of the study. The characteristics of noninvasiveness, lack of ionizing radiation, and good interstudy reproducibility are all distinct advantages for an imaging study intended to be used serially in children.

Congenital obstruction at the level of the main pulmonary artery, right ventricular outflow tract, or tricuspid valve requires a corrective procedure that involves construction of an atriopulmonary connection (Fontan procedure) or ventriculopulmonary conduit (Rastelli procedure) using native tissue and/or homograft material. These procedures can be complicated by insidious stenosis of the conduit, or the anastomotic site(s), and will benefit from periodic imaging examinations in addition to clinical follow up. The Fontan procedure has been evaluated

with the spin echo technique alone.⁶⁹ Addition of velocity-encoded cine MRI can provide further information regarding quantification of blood flow through the connection into the pulmonary arteries. This technique has demonstrated the normal biphasic pattern of blood flow, similar to venous flow, seen in atriopulmonary Fontans, or the normal monophasic pattern, seen in atrioventricular Fontans, thus confirming the success of the operation.⁷⁰ Rastelli conduits may also be complicated by stenosis, which is often difficult to evaluate with echocardiography because of the anterior location of the conduit in the chest. The velocity-encoded cine MRI technique has been applied in these patients to measure the gradient and to localize accurately the site of obstruction, providing a measure of the severity of the lesion which was superior to echocardiography.⁷¹ The Norwood⁷² and Jatene^{50,73} procedures have been evaluated similarly, and MRI has been shown to be equivalent to angiography, and superior to echocardiography, respectively.

Extracardiac conduits such as the Glenn (superior vena cava to the right pulmonary artery) and Blalock-Taussig (subclavian artery to the ipsilateral pulmonary artery) shunts also can be evaluated easily with spin echo techniques, often in a single imaging plane. Serial imaging studies are valuable to evaluate for size, course, and patency of these shunts, as well as growth of the pulmonary arteries.^{63,74}

6 THE FUTURE

The technology relevant to MRI of the heart continues to evolve. Consequently, the application of MRI in cardiovascular disease can be expected to increase further in the next several years.

Residency training in diagnostic radiology, University of California, Los Angeles. Fellowship training in cardiovascular imaging and MRI (supervisor Charles B. Higgins), University of California, San Francisco. Currently clinical instructor in cardiovascular imaging/MRI, University of California, San Francisco, Approx. 10 publications. Research specialties: MRI of acquired and congenital cardiac disease, MRA, and quantitative vascular flow measurements.

Charles B. Higgins. b 1944. B.S., 1963, Villanova University. M.D., 1967, Jefferson Medical College, USA. Residency training in surgery, University of California, Los Angeles, and in diagnostic radiology, University of California, San Diego. Fellowship training in cardiovascular radiology, Stanford University. Research training at the Cardiovascular Research Laboratory (supervisor Eugene Braunwald), University of California, San Diego. Currently Professor of Radiology, and Chief, Magnetic Resonance Imaging and Cardiac Imaging Sections, University of California, San Francisco. Approx. 450 publications. Research specialties: MRI of acquired and congenital cardiac disease, and strategies for detection of myocardial ischemia using MR contrast media.

Lung and Mediastinum MRI

Robert J. Herfkens

Stanford University School of Medicine, CA, USA

The utilization of MRI techniques for visualization of lung and mediastinal abnormalities has been greeted with great enthusiasm due to the excellent contrast resolution of MRI. However, the complex motions associated with those respiratory and cardiac events have posed significant challenges to the utilization of MRI for visualizing pulmonary and mediastinal abnormalities. The utilization of motion compensation techniques have greatly improved the image quality of MRI, and its intrinsic qualities have indeed provided unique diagnostic information about thoracic disease.

In order to compensate for the complex motions associated with the heart motion and blood flow, methods for coordinating the acquisition of the images in concert with the cardiac cycle have been developed.¹ Gating or triggering of the acquisition to the cardiac cycle has been obtained through a number of methods; primarily, electrocardiographic (ECG) gating methods have been employed.^{2,3} In addition, methods of plethysmographic or pulse oximeter methods have been utilized, but these are somewhat less precise in coordinating the acquisition with the cardiac cycle. The ECG signal triggers the magnetic resonance (MR) scanner as providing a consistent point in the cardiac cycle for initiating multislice or cine imaging. This, however, provides a limitation in imaging of the chest, as the R-R interval determines the repetition time of the scan. This provides a significant limitation to the flexibility of presenting imaging contrast. For an average heart rate of 60 beats per minute, the minimum repetition time would be 1000 ms. Depending upon the patient's physiologic status, the heart rate may vary quite greatly, thus having a significant effect on the overall image contrast, due to varying *TR* times.

Respiratory motion, which is also periodic, causes significant artifacts in MRI. These have a strong impact on chest images. The simplest solution to respiratory artifacts originally was to provide multiple signal averages, which blur the respiratory motion and, in general, improve the signal-to-noise ratio. These increases in imaging time, associated with respiratory averaging, are somewhat inappropriate on modern systems. Techniques that coordinate the phase encoding of the image acquisition with the respiratory cycle, so-called 'respiratory ordered phase encoding' or 'respiratory compensation', can significantly reduce the amount of respiratory artifacts without unduly increasing the imaging time. Recent fast imaging techniques with fast repetition times as short as 10 ms have allowed breath-held images of the chest. Although these images may introduce some blurring of the cardiac silhouette, improved definition of mediastinal and diaphragmatic structures have been realized.

Basic spin echo techniques gated to the cardiac cycle will provide relatively unique contrast within the mediastinum.

The basic contrast associated with relative *T*₁-weighted imaging shows fat as a relatively high signal intensity, with normal mediastinal structures, such as the esophagus and heart, with intermediate signal intensity.⁴ The intrinsic flow sensitivity spin echo images show a relative decrease in signal intensity of the vascular structures. In gated spin echo imaging, however, the signal intensity of major vessels may vary, depending upon when the specific image is obtained in the cardiac cycle. Those images obtained during systole have a relatively strong signal void, and those obtained during diastole may have significant intravascular signal, because of the relatively slow flow. Utilization of flow sensitive sequences, such as gradient-recalled imaging techniques, have improved the ability to differentiate intravascular slow flow signal from soft-tissue signals. Gradient-recalled images show an intrinsic sensitivity to flowing blood due to flow related enhancement, thus demonstrating an increase in signal intensity associated with flow. By utilizing gating with gradient-recalled sequences, phase-encoding signals can be advanced with each cardiac cycle, thus providing a cine image throughout the cardiac cycle, generating sensitivity to flow. In addition, phase contrast techniques have been applied to the cine technique, allowing the demonstration of velocity changes throughout the cardiac cycle (Figure 1). These phase contrast techniques have been used to characterize flow in major vascular structures and may be important in characterizing pulmonary artery flow abnormalities⁵ (Figure 2).

When using spin echo sequences, the repetition time is determined by the R-R interval. In order to obtain *T*₂-weighted images in the chest, techniques which would allow for the gating of the acquisition to multiple heart beats, which is every third or every fourth heart beat, allow for the acquisition of *T*₂-weighted data. In general, the utilization of *T*₁-weighted data has been superior for anatomic definition. The intrinsic contrast, as previously noted, where fat is bright and muscle and esophagus are dark, leave any other intermediate signal intensities as being pathologic. The relatively high contrast between flowing blood in spin echo images and other soft tissues also allows for excellent contrast to characterize other pathologic entities related to vascular involvement or improved definition of the spatial relationship associated with the relative signal void of vascular structures (Figure 3).

The ability of MR to generate any plane has been a significant advantage over conventional techniques, such as computerized tomography (CT). The use of coronal planes has significantly enhanced the visualization of abnormalities and the apices of the lungs, and has improved the visualization of lesions associated with the diaphragm. The ability to utilize oblique planes has been extremely helpful in characterizing pathologies associated with the aorta or other structures.⁶

Another major element which degrades images within the thorax is the susceptibility associated with the multiple air-water interfaces in the pulmonary parenchyma. This marked change in susceptibility has resulted in a very poor delineation of other abnormalities within the lungs themselves. A number of recent techniques have provided significant improvement in the visualization of pulmonary abnormalities; however, they still appear to be significantly less sensitive than CT for detecting pulmonary pathologies.⁷⁻⁹ The development of fast spin

Figure 1 (a) A gated T_1 -weighted spin echo image showing prominent soft tissue density along the lateral wall of the heart. This mass in a 32-year-old female was identified on chest X-ray. (b) Eight frames of a cine gradient-recalled imaging sequence from diastole through systole. The mass noted in (a) is shown with signal variations suggesting flow. (c) A cine phase contrast imaging sequence encoded in the superior to inferior direction corresponding to the image shown in (b). Note the significant change in signal intensity during systolic contraction in both the superior and inferior directions in the region of the mass, suggesting that this mass is a pulmonary arterial-venous malformation. (d) A pulmonary angiogram confirming the presence of a pulmonary arterial-venous malformation

Figure 2 Flow analysis of the right pulmonary artery flow pattern in a patient after lung transplant. This is the native lung and shows a pulsatile flow profile going from positive to negative throughout the cardiac cycle, showing a low net total flow to the lung. Such pulmonary flow analysis may be helpful in determining vascular compliance of the lung, as well as in relative ratios in blood flow in postoperative patients

echo imaging techniques has recently been shown to increase the sensitivity to pulmonary parenchyma abnormalities, such as metastasis. However, CT is significantly superior. Projection-reconstruction techniques can utilize extremely short echo times (as short as 100 μ s), and thus allow imaging of the pulmonary parenchyma or lung water associated with the pulmonary parenchyma¹⁰ (Figure 4). These techniques remain somewhat experimental but will allow for the demonstration of pulmonary parenchymal signals, which are less sensitive to the susceptibility generated within the lung. These signals represent excellent maps of lung water and show exceptional promise in improving MR's ability for characterizing subtle intrapulmonary abnormalities.

The utilization of paramagnetic contrast agents has also advanced the abilities of thoracic MRI to characterize a number of lesions.¹¹ The T_1 shortening effects of paramagnetic materials have provided the ability to enhance the differentiation of atelectatic from existing tumors as well as characterizing nonperfused cystic structures.

MRI has been valuable in characterizing a number of signal intensities related to tissues. The specific signal characteristics of hemorrhage have allowed the identification of short T_1 changes associated with methemoglobin in order to characterize hemorrhagic processes from pulmonary parenchymal diseases. Pulmonary hemorrhage appears as a relatively short T_1 of bright signal intensity on T_1 -weighted images. Hemorrhage into the mediastinum or associated with aortic dissections can be characterized due to the signal intensity changes associated with hemoglobin as it changes from oxyhemoglobin to deoxyhemoglobin to methemoglobin.

Figure 3 (a) A coronal-gated spin echo image showing the intimate relationship of a bronchiogenic carcinoma with the right upper lobe bronchus. (b) A gated spin echo image posterior to (a), showing a larger portion of the mass and possible association with the chest wall

The mediastinum contains relatively simple contrast relationships for MRI. The esophagus and heart remain intermediate in signal intensity, contrasted to the relatively high signal intensity on T_1 -weighted images of thoracic fat. The normal thymus appears as a signal of intermediate intensity; it generally decreases in size with age, and increases in signal intensity with fatty replacement. Of note is the fact that the thymus may rebound in adulthood due to some physiologic stress, thus providing an intermediate anterior mediastinal sig-

Figure 4 Comparison of images obtained with (a) conventional T_1 -weighted gated (1 R-R) multislice spinwarp ($TR \approx 750$ ms, $TE = 15$ ms, 256×2 NEX, scan time 7.6 min, using respiratory compensation and spatial presaturation) and (b) multislice Hadamard projection reconstruction ($TR = 200$ ms, $TE = 0.25$ ms, 512 views $\times$ 8 NEX, scan time 4 min). The images have been windowed to show the lung parenchyma, which causes the flow artifacts in (a), to appear abnormally intense. Note that the projection-reconstruction acquisition has intrinsically lower respiratory and flow artifacts, even without the compensation methods employed in (a), and despite the reduced scan time. The lack of respiratory motion artifacts with the projection-reconstruction sequence is critical to the successful visualization of lung parenchyma

nal intensity. This, in general, can be differentiated from most pathologic processes on the basis of morphology. Although MRI provides excellent tissue characterization, the ability of MRI in differentiating between benign and malignant changes within the thymus itself is somewhat limited. CT and MRI both provide an excellent technique for evaluating anatomic changes associated with thymic disorders.¹²⁻¹⁴

MRI provides an excellent method for identifying and characterizing abnormalities in the pulmonary hila. The sensitivity to flow associated with spin echo imaging and the increase in signal intensity from gradient-recalled images provide an excellent format for identifying soft tissue abnormalities in the hila. MRI appears to be significantly more sensitive than CT for the detection of these abnormalities; however, the characterization of these may be somewhat difficult.¹⁵⁻¹⁷ The pathologic nature of hilar and mediastinal lymph nodes remains largely based on the size of the individual lesions. MRI provides an excellent format for visualizing lymphadenopathy. The ability to image in the coronal plane has increased the sensitivity for the detection of aortapulmonary window adenopathy. The major advantage of MRI over CT is that the intrinsic contrast relationships allow identification of the lymph nodes and their separation from major vascular structures without the need to administer an iodinated contrast agent. Characterization of pathologies by T_1 - and T_2 -weighted images, however, has been somewhat disappointing. Both inflammatory and neoplastic adenopathy appear to have prolonged T_2 times. The primary mechanism for distinguishing between benign and malignant adenopathy remains that of lymph node morphology and size.^{18,19} Staging of bronchiogenic carcinoma with MRI has provided an excellent means of detecting mediastinal lymph nodes on an anatomic basis. Characterization of lymphomas has also benefited significantly from the detection of mediastinal lymphadenopathy, due to the excellent contrast characteristics of MRI. The relative T_2 prolongation associated with lymphomas has been identified, but its use remains limited due to the lack of ability to characterize changes other than

those based on size (Figure 5). The evaluation of patients with recurrent lymphoma has been suggested to be improved by the ability of MRI to characterize increased water content of nodes. In most treated lymphomas, there is a generalized decrease in size and signal intensity related to therapy. The recurrence of lymphoma can be characterized by either an increase in size or an increase in signal intensity. The increase in signal intensity in T_2 -weighted images has been suggested to be grounds for suspecting recurrence, and individual patients with changes in signal intensity or size should be assessed for recurrent disease.²⁰

The evaluation of bronchiogenic carcinoma is important in determining therapy and prognosis. MRI and CT both provide excellent anatomic images of the primary tumor as well as the ability to characterize the presence of lymphadenopathy. A specific problem for which MRI may provide improved specificity is in the associated changes in atelectasis associated with proximal bronchiogenic lesions.^{21,22} MRI has been suggested to be an excellent method for differentiation of obstructed atelectasis from the primary mass. The utilization of paramagnetic contrast material appears to provide significantly improved information over CT, and aids in differentiating mass from atelectasis.^{23,24} (Figure 6).

Mediastinal cysts can often be confused with neoplastic lesions. The specific characteristics of very long T_2 and very long T_1 associated with mediastinal cysts enable these lesions to be characterized by MRI. The relative homogeneity associated with these benign congenital cysts and their anatomic location provides specific clues as to their etiology. Mediastinal cysts can be divided into duplication cysts, neurenteric cysts, and pleuroparenchymal cysts. In general, they are specifically characterized by their long T_1 and long T_2 and relatively sharp margins. The additional use of an intravenous paramagnetic contrast material will characterize these lesions as being avascular.

Esophageal carcinoma represents a continuing diagnostic dilemma. The presence of the primary mass can easily be identified by the relative increase in soft tissue density associated with the esophagus. MRI provides an excellent method for the staging of esophageal cancer and characterizing the association with vascular structures. The obliteration of fat planes about the aorta and other adjacent vascular structures, such as the left atrium, can be extremely helpful in planning therapy. These changes, however, do not appear to have significantly impacted on the ultimate outcome of esophageal cancer (Figure 7).

Approximately 10% of parathyroid glands are ectopic. Two thirds of these appear to arise in the anterior mediastinum. In the presence of hyperparathyroidism unresponsive to resection of the cervical components of the thyroid glands, the mediastinum becomes the primary source. The behavior of hyperplastic parathyroid glands on MRI is characterized by a markedly prolonged T_2 relaxation time. This makes the identification of T_1 - and T_2 -weighted images extremely important. It should be noted that the identification of a markedly prolonged T_2 signal in the mediastinum should be separated from relatively slow flow in thoracic veins by the utilization of some form of gradient-recalled imaging sequence.

The excellent contrast characteristics of MRI provide an excellent means of staging of thoracic neoplasms. The sensitivity to direct invasion of vascular structures by obliteration of

Figure 5 (a) A gated T_1 -weighted spin echo image through the upper mediastinum. (b) A spin density gated image through the upper mediastinum. (c) A T_2 -weighted gated image through the upper mediastinum. Note the bulky adenopathy in the anterior mediastinum and the right paratracheal space. In addition, note the large lymph node in the right axilla. There are bilateral pleural effusions present, which give significantly variable signal intensities, as do all these images, to the relatively long T_1 and T_2 of the effusion, which is affected strongly by flow secondary to cardiac and respiratory motion. Note the difference in the degree of conspicuousness of the axillary node in the fat-suppressed image (d) and the significant difference in the signal characteristics of the mediastinal adenopathy. The fast spin echo image associated with both fat suppression and magnetization transfer effects will have significantly different contrast in this mediastinal adenopathy. The ability to characterize adenopathy, due to signal changes, remains a complex issue

associated short T_1 fat planes provides an excellent method (Figure 8). The ability of MRI to characterize changes along the thoracic wall provides a unique opportunity to demonstrate thoracic wall invasion. The short T_1 associated with subpleural fat and the relatively long T_1 of thoracic neoplasms give MRI great sensitivity in detecting thoracic wall invasion (Figure 9). These changes in thoracic wall invasion observed in both lymphoma and bronchiogenic carcinomas may significantly change therapy.²⁵ Either identification of the lesion as being nonresectable or the provision of information about thoracic wall invasions may significantly alter the radiation therapy planning. Similarly, the ability to provide coronal images of Pancoast's tumors may provide important information about resectability and therapy.^{26,27}

Pleural effusions are easily identified in MRI scans. The signal intensities were originally thought to provide important

information about transudative versus exudative behavior of pleural effusions. However, the strong effect of flow within the pleural effusions provides the dominant mechanism for signal changes in spin echo imaging. Free flowing pleural effusion may even appear as a signal void on spin echo images, and can easily be identified as areas of increased signal intensity and gradient-recalled images due to their flow related enhancement.²⁸

Pulmonary artery abnormalities, such as the presence of pulmonary emboli, have been identified as areas of increased signal intensity on spin echo images. MRI represents an excellent method for characterizing the presence of central pulmonary emboli. In general, chronic pulmonary emboli have intermediate signal intensity on both T_1 - and T_2 -weighted images. However, the presence of acute pulmonary emboli may be characterized by the presence of an extremely high

intensity signal on T_2 - and T_1 -weighted images due to the presence of methemoglobin in the thrombi (Figure 10). The flow sensitivity of MRI has been utilized to characterize pulmonary arteriovenous malformations. The relatively intermediate signal intensity seen on T_1 -weighted images may be present due to relatively slow flow. The sensitivity of gradient-recalled images or phase contrast methods has allowed the characterization of these pulmonary parenchyma abnormalities by demonstrating the flow within them (Figure 1).

In summary, the excellent contrast characteristics of MRI, associated with its sensitivity to flow, make it an excellent method for identifying and characterizing pulmonary and med-

iastinal pathologies. The relatively limited spatial resolution within the pulmonary parenchyma is a significant limitation; however, the superb contrast sensitivities have ensured the place of MRI in the identification and characterization of thoracic pathologies.

Figure 6 (a)–(d)

Figure 6 (a) A CT scan obtained from a patient presenting with a right-sided mass and large pleural effusion. (b) A gated coronal image through the same patient as in (a) following a thoracentesis. This image still shows a rather prominent mass, with occlusion of the right upper lobe bronchus. The question of primary mass versus atelectasis is often raised. (c) A gated transverse spin echo image through the mass. Note the relatively high signal intensity of this 'T₁-weighted image' in the periphery of this mass, the finding which is described in atelectatic lung. (d) A fat-saturated fast spin echo image showing marked heterogeneity in the mass but relatively clear delineation between the peripheral components and more central low intensity mass. (e) A T₁-weighted fat-saturated gated fast spin echo image through the same region as in (d) showing marked enhancement of the mass, as well as the adjacent pleura on this side

Figure 7 A gated transverse spin echo image through the midthorax shows a subcarinal mass associated with relatively subtle esophageal carcinoma. There is a fat plane between the aorta and mediastinal soft tissue, suggesting no definite invasion. Of more importance are the soft tissue densities in each lung field. These relatively hazy, ill-defined nodules are characteristic of metastatic disease on MRI. CT remains the primary method of screening for pulmonary metastases

Figure 8 A gated spin echo image through the upper mediastinum shows prominent anterior mediastinal adenopathy as well as a prominent para-aortic node. On the right-hand side there is pulmonary parenchymal consolidation and fibrotic changes secondary to prior radiation therapy. Shoddy mediastinal adenopathy is present. Of note is the absence of a significant signal void in the superior vena cava, due to vena caval occlusion

Figure 9 (a) A gated spin echo image through a bronchiogenic carcinoma of the right upper lobe. (b) A gated spin-density-weighted image through the carcinoma. (c) A STIR image obtained through the upper mediastinum. Note the excellent delineation on all images of the primary mass in relation to the pulmonary parenchyma. Paratracheal adenopathy is clearly visible on the spin echo images, but is somewhat obscured on the STIR images. The STIR image does, however, provide much better detail of the mass and its intimate association with the chest wall, suggesting chest wall invasion. In addition, the significant motion artifacts present on the STIR image are due to the relative difficulty of gating inversion-recovery images. The STIR images themselves are useful in investigating chest wall invasion but, due to the relative temporal inefficiency, may not be appropriate for all patients

Figure 10 A gated T_1 -weighted transverse image through the aortic arch, showing a very high signal intensity area on the left upper lung corresponding to a subacute pulmonary embolus

Marker Grids for Observing Motion in MRI

Leon Axel

University of Pennsylvania, Philadelphia, PA, USA

1 INTRODUCTION

Early in the development of NMR, it was noticed that motion could affect the NMR signal.¹ It was quickly understood that this reflected the fact that moving material carries its magnetization with it. If the magnetization is perturbed locally, that perturbed magnetization is carried with the material as it moves. This principle was applied in some early applications of NMR to the measurement of fluid flow.²⁻⁴

With the development of MRI, selective excitation was applied to the region to be imaged. The resulting local perturbation of magnetization within the slice being imaged led to intensity changes in the images of flowing blood or cerebrospinal fluid, due to ‘time-of-flight’ (TOF) effects.^{5,6} (See also articles on Flow in this Encyclopedia, listed in the Related Articles below.) These TOF effects due to selective slice excitation can be used for qualitative or quantitative evaluation of flow through the plane of the image. We will review here some aspects of using regional perturbation of the magnetization in planes *perpendicular* to the image to create magnetic tags. Subsequent imaging allows us to display directly the motion (of fluid or tissue) in the plane of the image during the time between tag production and image data acquisition, as a corresponding displacement of the tags in the image. We will review some aspects of tag production, approaches to tagged image analysis, and initial applications. While the phase shifts acquired by excited spins moving along magnetic field gradients can also affect their signal, we will not consider these effects here.

2 TAG PRODUCTION

When perturbed, the altered magnetization (excitation or saturation) in a tag will persist for times of the order of the relaxation time. An excitation tag can be produced with initial excitation of a plane perpendicular to the imaging plane and subsequent conventional position encoding in the imaging plane. These excited spins will be seen as a bright stripe in the image, representing the intersection of the initially excited plane with the imaging plane. Any displacement of the spins in the plane of the image between the times of initial excitation and subsequent position encoding will be seen as a corresponding displacement of the tagged stripe. This approach has been used to demonstrate fluid flow, with the excited spins detected either as a conventional spin echo⁷ or as a gradient echo.⁸ If conventional spin echo detection is used, the refocusing rf

pulse can be used to select the plane to be imaged. With gradient echo excitation tagging, a two-dimensionally selective ‘spike’ excitation could be used to restrict the tagging plane. The motion sensitivity of tagging depends on the time between excitation and readout. This, in turn, is limited by transverse relaxation to be of the order of the T_2 relaxation time, or T_2^* for gradient echo readout.

An alternative way to create tags is with local production of saturation or inversion in a plane or planes perpendicular to the image plane. The altered longitudinal magnetization will result in stripes with a correspondingly altered image intensity in a subsequent image acquisition, representing the intersections of the tagged planes with the imaging plane. Any displacement in the image plane between the times of tagging and imaging will be seen as a corresponding displacement of the tagged stripe in the image. In this case, tag persistence is limited by longitudinal relaxation so that displacement can be tracked for times of the order of the T_1 relaxation time (with initial inversion leading to longer tag persistence than initial saturation).

The local perturbation of magnetization can be created selectively. Selective tagging is analogous to slice selection excitation, with an rf excitation pulse with tailored frequency content applied in the presence of a magnetic field gradient, in order to excite only a desired plane perpendicular to the gradient. If only longitudinal magnetization tagging is desired, any remnant transverse magnetization from the tagging can be ‘spoiled’ by applying a further magnetic field gradient prior to excitation of the imaging plane. Multiple tagging planes can be created by applying the tagging process repeatedly at several locations or by tailoring the rf pulse to excite several locations simultaneously.⁹ The latter approach can allow more rapid production of tagging patterns, but may require more rf power. By following selective inversion tagging with a nonselective inversion pulse, we can create a tag pattern with bright stripes (where the magnetization has been driven back up toward equilibrium) against a darker background.¹⁰ Separate images of different tagging patterns can be combined to give the effect of having used a more complex tagging pattern.¹¹

The tagging pattern can also be created nonselectively. In this case, the magnetic field gradient is applied *between* nonselective rf excitation pulses.^{12,13} The resulting periodic phase variation along the direction of the gradient leads to a net periodic modulation of the magnetization along the direction of the gradient, or spatial modulation of magnetization (SPAMM). This is precisely analogous to the use of binomial pulses¹⁴ and related techniques in NMR spectroscopy for solvent suppression; in spectroscopy the corresponding periodicity of the suppression is usually chosen to be greater than the relevant spectral bandwidth. This spatially modulated magnetization, in turn, will be seen in a final image as a periodic stripe pattern along the direction of the tagging gradient. The spacing of the stripes will be determined by the strength and duration of the gradient pulses; the orientation of the stripes will be determined by the orientation of the tagging gradient. The relative position of the tag pattern along the gradient direction can be shifted by shifting the relative phases of the rf pulses. By using multiple rf pulses with suitable relative intensities, we can control the intensity profile of the resulting tagging pattern.

The result of one application of SPAMM is a set of parallel tagging stripes. Creating a second set at right angles to the first can produce a tagging grid.¹³ Images with tagging patterns of opposite polarity can be combined to increase the effective amplitude of the tags.¹⁵ Tags can also be created with tagging planes that are not perpendicular to the imaging plane, although the stripes may be blurred due to partial volume effects with the oblique intersection of the tagging plane with the slice being imaged.^{16,17} The SPAMM principle can be used with a continuous gradient if the rf pulses have sufficiently broad spectral content (are ‘hard’ enough) to excite the region to be tagged in the presence of the gradient.¹⁸ The SPAMM principle can also be applied in combination with selective excitation tagging to create periodic amplitude modulation along the tag.¹⁹

Saturation or inversion tags can be used as a preconditioning sequence incorporated into any imaging pulse sequence, much as a conventional inversion pulse can be used to add T_1 relaxation time weighting to images. For example, with cardiac-gated imaging, the cardiac-derived trigger can be used to control initiation of the tagging, and then imaging data can be acquired at subsequent desired delays into the cycle (Figure 1). The tag pattern will reflect any motion of the underlying tissue between the times of tagging and imaging. If used in conjunction with a rapid enough imaging technique, images can be acquired with suspended respiration, removing image degradation due to respiratory motion.^{11,20,21} With a further decrease in imaging time, motion of soft tissue structures can be evaluated with a voluntary motion initiated at the time of tagging (e.g. in response to the audible sound of the gradients used in the tagging sequence)¹⁰ and a ‘one-shot’ image acquired when the new position has stabilized but before the tags have faded too much.

3 TAGGED IMAGE ANALYSIS

Much qualitative motion information can be gained from visual inspection of the deformation of the tag pattern (Figure 2), particularly with a dynamic ‘cine’ display of images acquired with progressive delays after the tagging. However, there is the potential for further extraction of quantitative measures of motion from analysis of the displacement and deformation of the tags.

Motion can be considered as composed of rigid body motion (displacement and rotation) and deformation (‘strain’). The rigid body displacement is a property of material points. It is defined as the motion of the points relative to an external reference system, for example, the centroid of a ventricle (at a fixed time or moving with the ventricle), and will be affected by bulk motion of the structure of which a particular point is a part. In contrast, the ‘strain’ is a property of the material in a small region about a given point. It is defined as the relative change in length of material line segments passing through the point. As it depends only on the deformation of this region, it will be independent of the choice of external reference system. Another important difference between displacement and strain, as properties describing motion, is that whereas displacement is a vector quantity described by a magnitude and a direction, strain is a higher-dimensional *tensor* quantity that is orientation dependent. While a line segment oriented in one direction may be stretched a given fractional amount, other line segments passing through the same point in different directions will, in general, be stretched different fractional amounts, or even shrunk.

Although it would seem difficult or impossible to describe efficiently the full strain tensor, the strain in a small region around a point can be conveniently summarized by the ‘princi-

Figure 1 Tagged short axis images of the heart, (a) immediately after tagging at end diastole and (b) at end systole: chest wall (CW), right ventricle (RV), left ventricle (LV)

Figure 2 Superimposed positions of tag lines measured from images in Figure 1

pal strains' at the point. In general, a hypothetical unit sphere (circle in two dimensions) about the point in an initial state will be transformed by motion into an ellipsoid (ellipse in two dimensions). The three major axes of the ellipsoid (or two axes of the ellipse) will suffice to define the final length of any initial line segment. The lengths of these axes for an initial unit length are the 'eigenvalues' of the strain; their directions give the 'eigenvectors'.

For homogeneous deformation within a given region defined by a two-dimensional tagging grid, the rigid body motion and deformation motion variables can be calculated from the motion of the grid points. In particular, for a two-dimensional homogeneous deformation, the motion of the corners of a triangular region is sufficient to define the rigid body motion and strain within the triangle.^{22,23} An alternative approach to calculating the motion variables within a tagged region is to use finite element methods to fit the motion between the tags to a smoothly varying function of position; this model of the motion permits calculating the rigid body motion and strain at each point without requiring the assumption of homogeneous strain within each portion of the tagging grid. The motion data from two orthogonal sets of tagged images can be combined into one unified three-dimensional (3D) finite-element model and used to calculate 3D strains.²⁴ Note that in calculating motion from tagging grid points, it is generally not wise to use the coordinates of the intersections of tag lines with the boundaries of a moving object as distinct tagged landmarks, because through-plane motion of an obliquely oriented or tapered object can result in artifactual motion due to the change of the intersection of the boundary of the object with the fixed imaging plane.

When the amplitude of the motion is of the order of the spacing between tags, care must be taken to avoid confusing one tag for another in the deformed state. If this is a problem, additional images with a more widely spaced grid or at intermediate times can help resolve the ambiguity.

Tracking the sequential positions of multiple points in a tagging grid through multiple imaging slice locations can be a time-consuming and tedious process. The use of computer programs specifically designed for tag analysis can significantly speed up the analysis process²⁵. In particular, techniques to make the process of extraction of tag position from the images more automated can be very useful. These approaches can include means to match the tags to a 'template' of a model tag or tag grid intersection.²⁶⁻²⁸ Alternatively, various edge or contour tracking techniques can be used to track the tags.^{29,30}

Having derived a large amount of regional motion data from tagged images, we are faced with the problem of how to present it in a readily assimilated form. Visual display of the local values of motion variables as 'functional images' is an efficient and appealing approach to this problem, made practical by the continuously improving performance/cost ratio of computers with graphical displays. Scalar quantities, such as the magnitude of the displacement, can be relatively easily displayed, for example, as pseudocolor overlays on the images. Even here, however, the task of displaying the time evolution of motion in a three-dimensional object may require interactive dynamic display on a computer screen to convey fully the nature of the motion. Vector motion quantities, such as directed displacement, may require overlaying the display with symbols such as arrays of directed arrows. Higher order motion quan-

tities, such as strain eigenvectors, are intrinsically difficult to display fully on a flat screen or page, particularly for three-dimensional motions. Tensor properties may require display as lower order components such as the strain eigenvalues.

The reliability of tagged imaging studies as markers of the underlying motion has been validated with imaging studies of phantoms with independently known motions. This includes both phantoms undergoing only rigid body motion³¹ and phantoms undergoing deformation.³² As expected, the tags do move with the underlying material.

4 APPLICATIONS

The development of tagged imaging methods and of methods for the analysis of the resulting images is still ongoing. However, experience is being gained with initial applications to a variety of motion studies, including flow imaging, regional heart wall motion, and other soft tissue deformation.

A simple, but very useful, application of tagged imaging to flow studies is simply to detect the presence of flow. Although the usual TOF and phase shift effects of motion seen in conventional MRI are generally sufficient to distinguish flowing blood from static thrombus in MR images, it is not uncommon to have difficulty distinguishing slow flow from thrombus. Tagging methods provide a straightforward way to increase the sensitivity of MRI to slow flows. If grid saturation tags are created in the region of question as part of a cardiac-gated imaging sequence, and a delay of 200 ms or so is allowed to elapse between tagging and image data acquisition, any fluid motion of the order of a pixel or more during this interval will result in a visible shift and distortion of the tag pattern, or even complete smearing out of the tag pattern due to shearing

motions of the fluid.¹² For example, in pulmonary artery embolization, the resulting slow flow can be difficult to distinguish from the emboli; SPAMM can be very helpful in defining the emboli.³³

The problem of visualizing patterns of fluid flow is a long standing and important one, with many different solutions such as the injection of opaque tracers into transparent flowing fluids. The use of tagged MRI provides a new and potentially powerful tool for the study of flow patterns. The tagging process does not disturb the flow in any way, MR tagging can be employed with opaque fluids, there is no distortion due to refraction, and images are obtained in registered 3D sectional planes. In addition to biological fluid flow applications, there may be useful engineering and industrial applications.^{34,35}

An important area of potential application is to the study of regional heart-wall motion. Traditional imaging methods of studying cardiac function have been invasive or limited in the kinds of motion data they provide. The lack of trackable landmarks within the heart wall, and the few surface landmarks, have largely limited heart-wall motion analysis to the study of the motion of the endocardial surface or of wall thickening. This analysis has been further limited by the uncertainty about what is the appropriate reference system against which to measure the surface motion, and by the potential error due to through-plane motion of the curved and tapering heart wall. Within-wall and nonradial components of heart-wall motion can be evaluated at selected points through biplane imaging of radioopaque markers embedded in the heart wall, but the difficulty of tracking many markers and the invasive nature of the embedding process has limited such studies to relatively few markers and precluded routine clinical application of these methods. In contrast, tagged MRI is completely noninvasive and permits a full tensor analysis of motion patterns within the heart wall.

Figure 3 As in Figure 1, but for a patient with diffuse hypertrophic cardiomyopathy

As the cardiac motion data provided by MRI are new, initial applications of tagged MRI to the heart have studied the normal patterns of regional wall motion.^{36,37} Application to the study of abnormal motion patterns in hypertrophy due to pressure overload³⁸ or hypertrophic cardiomyopathy³⁹ is attractive both because of their clinical importance and because of the relative ease of studying motion within thicker heart walls (Figure 3). Ischemic heart disease is another area of potential significance, as MRI-derived strain measures may provide a more precise and sensitive way to characterize regional contractile dysfunction than conventional wall motion studies. This may lead to a better understanding of phenomena such as the impairment of function seen in the perinfarct zone.

Other soft tissue structures, such as skeletal muscle, may be studied in a manner similar to the heart wall. They can be imaged either with repetitive motions using a modified, tagged, cardiac imaging sequence and an appropriate trigger signal,¹⁷ or with a 'one-shot' tagged imaging sequence.¹⁰ While it is still early in the development of these areas of application, the power of tagged MRI to provide a noninvasive means to analyze other 'hidden' motions should lead to a new understanding of normal and abnormal function, and hopefully to a useful new diagnostic tool.

NMR Spectroscopy of the Human Heart

Paul A. Bottomley

Johns Hopkins University, Baltimore, MD, USA

1 INTRODUCTION

The heart is the largest consumer of energy per gram of tissue, and defects involving energy metabolism, including energy supply and demand, are central to much disease of the heart. It is inevitable, therefore, that human cardiac spectroscopy has focused on the energy metabolites that are NMR detectable. Phosphorus (^{31}P) NMR spectroscopy (MRS) can see adenosine triphosphate (ATP), the fundamental energy currency of the body, and phosphocreatine (PCr), a reservoir of cellular energy, in the heart, as well as the metabolic by-product inorganic phosphate (P_i). The signal-to-noise ratio is about 1×10^{-5} or 2×10^{-5} of that of the proton (^1H) NMR signal from muscle water (from the same volume), at the same magnetic field strength.^{1,2} PCr and ATP cannot therefore be imaged with the same spatial resolution, signal-to-noise ratio, and scan time as tissue water protons in the same magnetic field. However, with compromises in spatial resolution and scan time, PCr and ATP can be seen in anterior wall volume elements (voxels) as small as 8 mL in the anterior myocardium.³

PCr and ATP are linked via the creatine kinase (CK) reaction:

whereupon inorganic phosphate (P_i) may be formed as

The total creatine pool (CR) comprising unphosphorylated (Cr) plus PCr is also detectable in the heart via its *N*-methyl resonance at 3.0 parts per million (p.p.m.) using ^1H MRS, with a current resolution of 3–9 mL in scan times of <10 min.⁴ Consequently, a combination of ^1H and ^{31}P MRS could potentially provide a near-complete picture of CK metabolism in the heart. Under anaerobic conditions, such as may occur in ischemic heart disease in regions of the heart supplied by blocked arteries,⁵ a transient mismatch between oxygen supply and demand can cause excess PCr consumption to maintain adequate ATP, along with possible elevations in P_i . This is manifested as reductions in PCr/ATP, PCr/ P_i , and/or ATP/ P_i in the corresponding ^{31}P MRS during the ischemic episode. The rapid depletion of ATP and PCr levels assayed after coronary occlusion or low-flow ischemia has been demonstrated in animal models.⁶ Biochemical assays of biopsies taken at surgery have also demonstrated chronic reductions in the levels of PCr, Cr, and creatine kinase activity in patients with dilated cardiomyopathy (DCM), hypertrophy, and coronary artery disease (CAD).^{7,8} These findings link changes in energy metabolism to

contractile dysfunction, but in the absence of evidence of active ischemia.⁹ Thus, the levels and ratios of PCr, ATP, CR, Cr, and P_i measured by ^1H and ^{31}P MRS may be useful indices of supply-side myocardial energy metabolism.

To date, ^{31}P NMR has been applied extensively in studies of patients with cardiomyopathies, including DCM, hypertrophic cardiomyopathy (HCM), and pressure overload left ventricular hypertrophy (LVH); patients with transplanted hearts, in an attempt to assess histological rejection; and patients with CAD and myocardial infarction, including exercise stress testing of patients with reversible ischemia. The literature on ^{31}P NMR of the heart has recently been reviewed in detail.¹⁰ Abnormalities of varying extents in the phosphate metabolites have been reported in all of these disease states. In particular, the variability of findings in cardiomyopathy, and the results from transplanted hearts, suggest the existence of confounding variables that are as yet incompletely understood. However, quantitative studies are approaching a consensus on the true PCr/ATP ratio for human heart, and there are preliminary values reported for the PCr and ATP concentrations, the intracellular pH, and the forward CK reaction rate, and flux. Quantification of P_i has proved difficult because of the presence of neighbouring blood 2,3-diphosphoglycerate (DPG) resonances. Partial saturation effects and contamination from blood and chest muscles are probably the main sources of discrepancy amongst reported myocardial ^{31}P NMR PCr/ATP data.

^1H NMR spectra from the human heart are dominated by water and fat resonances, but metabolites such as CR can be measured either relative to water, or as concentrations.⁴ CR appears to be depleted in myocardial infarction,⁴ and alterations are also anticipated in cardiomyopathy and heart failure.⁹

NMR spectroscopy studies of the human heart with nuclei other than ^{31}P or ^1H are scarce. Carbon (^{13}C) NMR potentially provides access to glycolytic and citric acid cycle metabolites such as lactate and glutamate but has the disadvantage of low NMR sensitivity and a 1.1% natural isotopic abundance. This effectively prevents their detection at natural abundance with current technology without resorting to ^{13}C -enriched substrates.² Fatty acid resonances are the main contributors to the natural abundance ^{13}C human heart spectrum, and pericardial fat is probably a dominant contaminant, but glycogen may be discernible with ^1H decoupling and NOE.¹¹ While strictly not spectroscopy since there is usually only a single resonance, sodium (^{23}Na) NMR has been performed in human heart^{12,13} and has potential for detecting sodium increases in reperfused infarction where sodium–potassium pump function is lost.¹⁴

2 METHODS

2.1 Localization

Localized ^{31}P NMR spectroscopy of the human heart was first reported in 1985.¹ That study, and all those since, employed surface detection coils placed on the chest closest to the anterior myocardium. Myocardium was distinguished from chest wall using MRI slice selection (the depth resolved surface coil spectroscopy, or DRESS, technique), and ^1H MRI was

used for tissue identification. While an unlocalized surface coil study of the chest of an infant with congenital cardiomegaly was also reported in 1985,¹⁵ the first studies of heart patients with localized spectroscopy protocols were not published until 1987.^{16,17} These were limited to two to four patients with hypertrophic cardiomyopathy or recent myocardial infarction, and localization was afforded by rotating frame zeugmatography (RFZ), which uses B_1 gradients, or by the DRESS technique.

Full three-dimensional MRI gradient localization of ^{31}P NMR spectra to single voxels in the heart via the image selected in vivo spectroscopy (ISIS) technique appeared in 1988.¹⁸ Multiple voxel, chemical shift imaging (CSI) studies of the heart using MRI phase-encoding gradients in one or more

dimensions were published around 1990.^{5,18,19} These spectroscopy localization techniques are reviewed in greater detail elsewhere (see *Chemical Shift Imaging*, *Selective Excitation in MRI and MR Spectroscopy*, and *Single Voxel Whole Body Phosphorus MRS*), and have various advantages and disadvantages. For example, a problem with three-dimensional CSI is that the large number of phase-encoding steps required to encode the entire sample volume sets a minimum scan time, which may not be compatible with clinical study protocols of limited duration such as in stress testing for myocardial ischemia. One-dimensional CSI and RFZ can be completed faster, but at the expense of the fuzzy localization afforded by the surface coil in the two dimensions that are not gradient encoded. An example of a one-dimensional CSI data set and the corre-

Figure 1 (a) Typical axial ^1H surface coil image of the chest and heart of a normal volunteer, annotated to show the location of eight 1 cm thick coronal slices localized in the spectroscopy exam. (b) Cardiac-gated one-dimensional CSI surface coil ^{31}P NMR spectra from the slices show a reference peak from a vial embedded in the coil (slices 9, 10), chest muscle (slices 12, 13), and myocardium (slices 14–16). Scan time for the spectra was about 12 min, in a clinical 1.5 T scanner. (Reproduced by permission of the Radiological Society of North America from Bottomley et al.²⁰)

sponding annotated cardiac image is shown in Figure 1.²⁰ Use of single voxel methods such as DRESS or ISIS requires accurate selection of a suspected region of abnormality a priori: incorrect voxel selection for a stress test, for example, could result in a missed finding for reversible ischemia.

¹H NMR spectroscopy studies of myocardial CR in patients to date have been performed using the single voxel point-resolved surface coil spectroscopy method (PRESS)²¹ and the stimulated echo method (STEAM)²² with water suppression. Each method localizes a spin-echo or stimulated echo NMR signal to a voxel defined in all three dimensions by the use of three spatially selective NMR pulses (90°–180°–180° for PRESS; 90°–90°–90° for STEAM).

2.2 Coils and NOE

A typical experimental cardiac ³¹P NMR surface coil probe is pictured in Figure 2.²³ When the sample is the dominant source of the noise detected by the surface coil, the coil diameter should be chosen roughly equal to the depth of the tissue of interest. This leads to heart ³¹P detectors with typical diameters of 6–12 cm for the anterior wall to mid-wall. Preferably, the signal is excited with a separate, larger rf coil to minimize spatially dependent distortions due to B_1 inhomogeneity.²³ Additional ¹H MRI coils ensure correct ³¹P detection coil placement, which is critical because of the limited range of sensitivity of the surface coil, and possible avoidable contamination from nearby tissue, especially chest muscle.

Sensitivity improvements of up to about $\sqrt{2}$ compared with the best positioned surface coil, and the need for careful positioning is relaxed if phased-array surface detection coils are

used.²⁴ This technology is in use in MRI,²⁵ and has been implemented in ³¹P studies of normal volunteers,²⁴ but not yet in patient studies.

Other factors offering potential sensitivity gains are the use of a prone, as opposed to supine, patient orientation, to bring the heart closer to the detection coil(s);²³ synchronization of NMR acquisitions to the cardiac cycle (see *Cardiac Gating Practice*); and ¹H NOE.²⁶ At 1.5 T, NOEs of $\eta = 0.61 \pm 0.25$ for PCr, $\eta = 0.6 \pm 0.3$ for γ -ATP, and $\eta = 0.3 \pm 0.2$ for β -ATP have been reported for the human heart.²⁶ Because of the differences in η for PCr and ATP, the NOE may distort the PCr/ATP ratio by up to 20%, necessitating a correction for quantitative intersite comparisons.²⁶

3 QUANTIFICATION

3.1 Myocardial PCr/ATP Ratio

If the PCr/ATP ratio is the most important metabolic index that ³¹P NMR can reliably detect in the heart, it is important to establish its normal range for inter- and intralaboratory comparisons. However, published values from healthy volunteers range from 0.9 ± 0.3 ²² to 2.1 ± 0.4 .²⁸ Why the difference? There are two main causes. First, data are distorted to varying extents by partial saturation effects that result from the use of pulse sequence repetition periods, TR , that are comparable to or less than the T_1 values of PCr and ATP. Differences in the T_1 values of the two moieties produce differential distortion of PCr/ATP.²⁹ The 95% confidence intervals for published T_1 values are given in Table 1.^{17,19,26,30–35} With a ratio of the T_1

Figure 2 The cardiac ³¹P NMR surface coil probe used to acquire the localized ³¹P and ¹H NMR data in Figure 1.²³ The patient lies prone on the padded coil set (left), which is positioned on the patient table in the center of the whole body NMR magnet. The coil set comprises a square base with a 0.40×0.40 m ³¹P transmit coil (lower left), and a smaller probe containing a 0.065 m mean diameter spiral ³¹P detector coil, and a 0.08×0.13 m figure-8 ¹H receiver coil, used for imaging and shimming (right). Black strips (right) are Velcro, permitting the smaller probe to be positioned at will. Passive diode circuitry minimizes coil interactions²³

Table 1 Phosphorus-31 NMR Measurements of Phosphate Metabolites in Normal Volunteers

Parameter	Value	Reference
$T_1(\text{PCr})$	4.37 ± 0.48^a	30
$T_1(\gamma\text{-ATP})$	2.52 ± 0.45^a	30
$T_1(\beta\text{-ATP})$	2.28 ± 0.54^a	30

NOE of PCr at 1.5 T	0.61 ± 0.25	26
	0.6 ± 0.1	35
NOE of ATP at 1.5 T	$0.6 \pm 0.3 (\gamma\text{-ATP})$	26
	$0.3 \pm 0.2 (\beta\text{-ATP})$	26
	$0.4 \pm 0.2 (\gamma\text{- and } \beta\text{-ATP})$	35

CK, creatine kinase; γ -ATP and β -ATP, γ - and β - phosphates of ATP.

^a95% confidence intervals.

values of PCr and ATP of about 1.9, the distortion or saturation factor, F , by which the PCr/ATP ratio measured in the short TR experiment must be multiplied by to yield the true myocardial PCr/ATP ratio, will vary between 1 and ~ 2 , depending on TR and the NMR pulse flip angles.²⁹ Thus, measurements that are corrected for partial saturation can differ from those that have not, by up to a factor of about two.

Correction of experimental PCr/ATP values for partial saturation can be done by two methods. First, F can be calculated using known myocardial T_1 values and a measurement of the experimental NMR pulse flip angle (e.g. with equation (2) of Bottomley et al.).²⁹ Due to time constraints, T_1 values are usually either measured on a separate group of individuals, or else published values are adopted. Second, F may be measured directly from the ratio of spectra acquired under partially saturated conditions and fully relaxed conditions. The unlocalized, uniformly excited signal detected by a surface coil on the chest is sufficiently sensitive to permit the measurement of saturation factors in about 6 min, which can easily be incorporated into the study protocol.^{5,29} This use of an unlocalized saturation factor depends on the assumption that $T_1(\text{PCr})/T_1(\text{ATP})$ is essentially the same in the chest and heart tissue that contribute to the unlocalized spectrum.²⁹ The assumption is consistent with the available data,³⁰ and errors resulting from differences in the ratio can be minimized by using small or Ernst flip angles for excitation.

The second, lesser source of scatter in the reported myocardial PCr/ATP values is that of blood which contains ATP but no PCr. This reduces the apparent PCr/ATP ratio in voxels that intersect the ventricles.³⁶ The PCr/ATP ratio can be corrected for blood ATP contamination by measuring the amount of blood using the blood DPG signal present in the spectrum

as a marker. DPG has a characteristic doublet at 5.4 and 6.3 ppm, near P_i ¹⁷ and other phosphomonoesters (PMs). The amount of ATP added by blood is estimated from

$$\text{corrected ATP} = \text{contaminated ATP} - 0.5 \times$$

$$([\text{ATP}]/[\text{DPG}]) \times \text{total DPG signal} \quad (3)$$

where $[\text{ATP}]/[\text{DPG}] \approx 0.30$,^{33,37–39} and remembering that DPG has two phosphates.

Blood ATP corrections typically increase PCr/ATP values by a relatively small amount, $13 \pm 6\%$.^{20,33,36,39,40} Potential problems with the correction may arise from differences between the T_1 of ATP and DPG for short TR protocols (possibly offset, however, by the effect of inflowing unsaturated blood), variations in the blood ATP/DPG ratio with localization method and patients,⁴¹ and possible contamination of DPG by P_i or PMEs, which would tend to cause overestimation of the amount of blood contamination.

Considering only those human studies in which both saturation and blood corrections were performed^{20,31,33,36,40,42–48} or in which blood contamination was ruled out,³ a consensus is emerging on the normal myocardial PCr/ATP value, as evident in Table 2. The mean value is 1.81 ± 0.14 , omitting the highest and lowest values. This should represent the best current estimate for the true PCr/ATP ratio in the normal human heart, since tissue ATP and PCr appear to be 100% NMR visible.^{49,50}

3.2 PCr and ATP Concentrations

Tissue [PCr] and [ATP] can be determined by combining the fully corrected PCr/ATP ratio from a voxel, with a measurement of the NMR signal from a concentration reference and a measurement of the volume of myocardium present in the voxel. The reference may lie outside of the subject, which requires that corrections be made for differences in field strength and sensitivity of the NMR coils at the two locations.¹⁶ Alternatively, a reference located at the same position as the heart may be observed in a separate experiment in

Table 2 Some Corrected Normal Human Myocardial PCr/ATP Ratios

Value	Field (T)	Reference
1.80 ± 0.21	1.5	36
1.93 ± 0.21	1.5	20
1.8 ± 0.1	4.0	3
1.95 ± 0.45	1.5	40
1.65 ± 0.26	1.5	33
1.85 ± 0.28	1.5	42
1.8 ± 1	1.5	31
1.71 ± 0.13	1.5	39
1.98 ± 0.07	1.5	43
2.02 ± 0.11	1.5	44
1.42 ± 0.18	1.5	45
1.61 ± 0.18	1.5	46
2.46 ± 0.53	1.5	47
1.6 ± 0.3	2.0	48

which differences in coil loading are taken into account.³¹ The tissue volumes must again be estimated by MRI, which may introduce weighting errors when the coil sensitivity is nonuniform across the localized volume.

A quantification method that does not require tissue volumetry employs measurements of the ^1H signal from water, s_W , as a concentration reference, using the identical localization sequence.³² The water signal is recorded with the same ^{31}P coil used to measure the PCr and ATP metabolite signals, s_P ; as a result, both ^{31}P and ^1H spectra are acquired with essentially the same B_1 profile. This is possible because of the enormous concentration advantage of the water signal compared with the metabolites. The method requires calibration with a phosphate reference to determine the ratio of the ^{31}P signal per phosphate to the ^1H signal per proton, C_{PH} , as well as knowledge of the myocardial tissue water content $[W]$, which appears to be relatively constant.⁴ The metabolite concentration in a voxel is calculated from:

$$[P] = \frac{2s_P[W]C_{\text{PH}}}{s_W} \times \left(\frac{F_P E_P}{F_W E_W} \right) \quad (4)$$

where $F_P F_W$ are the saturation factors and E the factors accounting for signal decay during TE (e.g. $E = \exp\{TE/T_2^*\}$ where T_2^* is the transverse signal decay time) with subscripts W for water, P for the metabolite (subscript P). The factor of 2 accounts for the two protons on water. The value of C_{PH} is determined in a separate experiment using a standard solution of phosphate.³² The tissue water signal can be corrected for contamination from water in ventricular blood and in pericardial fat via a ^{31}P DPG measurement and a measurement of the fat resonance in the ^1H spectrum, respectively. The contaminating water signal from ventricular blood is:

$$S(\text{blood}) = \frac{S(\text{DPG})W_B C_{\text{PH}}}{[\text{DPG}]} \times \left(\frac{F_{\text{DPG}} E_{\text{DPG}}}{E_B} \right) \quad (5)$$

The contaminating water signal from fat is $LS(\text{CH}_2)$, where $S(\text{CH}_2)$ is the lipid ^1H signal, and L is the water content of fat, which is about 15%.³² The corrected water signal to use in equation (4) is:

$$s_W = (\text{measured water signal}) - S(\text{blood}) - LS(\text{CH}_2). \quad (6)$$

Concentrations reported to date for the human heart are in fair agreement and are summarized in Table 1.

3.3 Total Myocardial Creatine

The detection of the N -methyl ^1H resonance of CR at 3.0 ppm provides a means of quantifying myocardial CR.⁴ Unlike PCr/ATP ratios, CR cannot be reliably measured as a ratio from a single ^1H acquisition relative either to water, which is normally suppressed, or to fat resonances, which are often variable because of contamination from pericardial fat. A solution is to acquire two consecutive ^1H spectra under the same conditions, with and without water suppression. The CR peak in the water-suppressed spectrum is measured relative to the water peak in the unsuppressed spectrum. Because ^1H sensitivity is high and because the ^1H T_1 values are shorter than for ^{31}P , the experiment can essentially be done fully relaxed. The CR/water ratios measured with the same STEAM or PRESS timing par-

ameters can be used for patient comparative studies.⁴ The normal CR/water ratio is about 1.3×10^{-3} . Such ratios can be translated into absolute concentration measurements using the known myocardial tissue water content and correcting for the signal loss caused by the STEAM or PRESS echo delay, represented by the E factors as in equation (4).⁴

$$[\text{CR}] = \frac{2s_{\text{CR}}[W]}{3s_W} \times \left(\frac{F_{\text{CR}} E_{\text{CR}}}{F_W E_W} \right) \quad (7)$$

with the extra factor of 3 for the N -methyl protons.

The initial ^1H NMR estimate for normal human heart $[\text{CR}]$ is $28 \pm 6 \mu\text{mol (g wet wt)}^{-1}$, which is consistent with canine and human necropsy studies.⁴ Concentrations reported to date for the human heart are in agreement, and summarized in Table 1.

3.4 P_i , pH, and Creatine Kinase Reaction Kinetics

Intracellular pH can be measured from the chemical shift of the P_i resonance, which varies from 3.7 to 5.2 ppm relative to PCr over a pH range of 6.0–7.3.⁵¹ In the normal heart, P_i is small and difficult to resolve unambiguously from blood DPG. It is probably better described by inequalities¹⁷ (Table 1). Even with ^1H decoupling, which may reduce the linewidths of the DPG signals and permit a less ambiguous determination of any neighboring P_i , P_i still appears undetectable in about half of the normal subjects studied.³³ When detectable, the normal myocardial pH is about 7.15 (Table 1). It is also possible that P_i is partially NMR invisible.^{49,50} It is unlikely, however, that P_i and pH measurements are contaminated by P_i in blood,⁵² since P_i is imperceptible in ^{31}P spectra from human blood^{39,41} and the $[P_i]$ in whole human blood is listed as only 0.08 mM.⁵³

The flux of PCr through the creatine kinase reaction [see equation (1)] in the heart can be measured using the saturation transfer NMR experiment.³⁴ The experiment involves acquisition of ^{31}P spectra while the γ -phosphate resonance of ATP is being saturated, for example, by application of a long rf pulse tuned to its resonant frequency. When ATP is saturated, the PCr signal declines as PCr is converted to ATP via the forward reaction, in the absence of any refreshment by unsaturated phosphates produced via the reverse reaction. The ratio of PCr signals measured with and without saturation is directly proportional to the first-order rate constant, in units of the T_1 of PCr in the presence of the saturating radiation. Studies in a 4 T whole body instrument indicate that about half of the PCr is turned over per second (Table 1), consistent with data from animals.³⁴

4 PATIENT STUDIES

Some data from human heart ^{31}P NMR studies of patients are summarized in Table 3.^{5,17,20,28,31,33,36,39,40,42–44,47,48,54,55}

4.1 Cardiomyopathy

Evidence anticipating reductions in myocardial high energy phosphates in human cardiomyopathy and hypertrophic disease comes from ^{31}P NMR studies of animal models,^{56–61} and

Values are mean ± SD. Data from abstracts are omitted. MD, muscular dystrophy; BB, cardiac beri-beri; CA, cardiac amyloidosis; MI, myocardial infarction. Controls were normal, or LVH patients not in heart failure (indicated by ^a), ⁵⁴ patients with dilated cardiomyopathy NYHA class < III failure,⁴⁶ or patients with no rejection.⁶² Statistical analysis versus controls or at rest:⁵ **P* < 0.001; ***P* < 0.01; ****P* < 0.05.

biochemical analyses of patient biopsies taken at surgery.^{7,8} Human in vivo ³¹P NMR studies have demonstrated statistically significant reductions in anterior myocardial PCr/ATP ratios in a group of patients with cardiomyopathies due to specific disease (muscular dystrophy, beri-beri, amyloidosis);²⁸ in patients with HCM;^{28,33,39,47} in patients with valve disease who were undergoing treatment for heart failure;^{44,48,54} and in patients with DCM who were in heart failure [New York Heart Association (NYHA) clinical classification for heart failure ≥ II].^{36,40,43} One report found a significant negative correlation between the NYHA classification for failure, and the myocardial PCr/ATP ratio.⁴⁰ Also, in patients whose NYHA classification was improved by drug therapy, myocardial PCr/ATP values recovered,⁴⁰ while patients with significantly reduced PCr/ATP ratios had a poorer survival rate compared with patients with normal PCr/ATP ratios, suggesting that the ratio may be of prognostic value.⁴³

A number of other studies have reported no statistically significant changes in myocardial PCr/ATP in LVH,^{27,28} or DCM,^{27,28,33,62,63} although possible correlations between reduced myocardial PCr/ATP ratio and the NYHA heart failure classification⁴⁰ were not explicitly ruled out by these studies. The findings are reviewed in detail elsewhere.¹⁰ Except for the NYHA classification, PCr/ATP ratios have generally correlated weakly with etiology and functional indices of disease severity

such as the left ventricular ejection fraction or fractional shortening although such links may be proved with ongoing studies.⁴⁸

The factors responsible for the differences in the significant findings for PCr/ATP ratios in cardiomyopathies are probably (i) variations in the range and severity of heart failure in patient study populations, and (ii) variations in statistical sensitivity. Regarding the former, it appears that averaging results from patients in mild and severe failure, or from a group of patients in predominantly mild failure, can mask significant PCr/ATP changes,⁴⁰ and that abnormalities might only be seen in subsets of patients in more advanced stages of heart failure.⁵⁴ With respect to the second factor, it should be noted that in all studies of HCM, DCM, and LVH so far, the mean myocardial PCr/ATP ratios were lower by 2–54% relative to the corresponding normal control groups with varying statistical significance.¹⁰

The ³¹P NMR data linking PCr/ATP changes to heart failure would indicate that abnormal myocardial PCr/ATP ratios may first become detectable in DCM and LVH between NYHA classes II and III,^{40,54} which is the point at which physical activity is limited by fatigue, and accompanying symptoms such as palpitation, or dyspnea. This is consistent with studies that conclude that the ability of the cell to sustain adequate levels of ATP is compromised only in the more advanced stages of

failure.⁶⁴ One hypothesis is that the reduced energy reserve, as demonstrated by the reduction in myocardial PCr/ATP ratios seen by ³¹P NMR, and by the decreases in myocardial creatine and creatine kinase activity evident in surgical biopsies, may limit the ability of the heart to do work, and lead to contractile dysfunction.⁹ On the other hand, in at least two studies of HCM,^{15,33} the PCr/ATP ratio was reduced in the absence of a link to heart failure, so it is possible that there are differences between HCM, and DCM and LVH.

In the clinic, ³¹P NMR might help identify patients in heart failure where physical activity or diagnosis is complicated by other conditions, including age⁵⁴ and lung disease. In patients with valve disease, the detection of metabolic abnormalities might find use in surgical planning to minimize permanent injury and maximize benefit.⁶⁵ Further work is needed to define where, specifically, the benefits lie.

4.2 Heart Transplant Patients

The idea that changes in myocardial metabolite ratios might predict histological rejection in human heart transplants stems from animal ³¹P NMR studies, usually of nonimmunosuppressed allografts, which showed metabolic changes prior to the occurrence of histological evidence for acute rejection in the first week or so posttransplantation.^{66–70} In the management of heart transplant patients, the standard criterion for assessing the existence of significant allograft rejection of severity sufficient to warrant augmentation of immunosuppressive therapy is histological evidence for myocyte necrosis in endomyocardial biopsies acquired during regular cardiac catheterization procedures. While some earlier conference reports on ³¹P NMR studies in transplant patients dating from 1988 show reduced myocardial PCr/ATP and PCr/P_i ratios in transplanted hearts, the success with which ³¹P NMR can reliably predict the outcome of histological evaluations is mixed.

The first published paper on 19 ³¹P NMR examinations of patients studied up to 5.5 years posttransplantation did find significantly lower resting anterior myocardial PCr/ATP ratios relative to normal controls, consistent with the animal studies.^{10,20} However, the results showed agreement between ³¹P NMR abnormalities and histological evidence for necrosis in only about 60–70% of examinations,²⁰ suggesting that ³¹P NMR is not a precise predictor of significant histological rejection in many transplant patients.

To date there is no firm evidence linking the finding of significant reductions in the myocardial PCr/ATP (and possibly PCr/P_i) ratio in transplanted hearts to other factors such as hypertrophy, or CAD involving the major vessels. However, one conference report of 13 transplant recipients on 71 occasions found reduced PCr/ATP ratios in the first few weeks after transplantation, suggesting that lower creatine levels or injury or edema following surgery may be possible causes.⁷¹ The observation that PCr/ATP ratios may not precisely predict histological rejection is likely to reflect fundamental differences between histological and metabolic indices. In particular, myocyte necrosis would not cause altered PCr/ATP ratios because dead cells can contribute no high energy phosphates, whereas necrosis is important in histological evaluation. If the PCr/ATP reduction is associated with rejection, it may reflect an earlier phase of the process, which would not be inconsistent with the observed PCr/ATP reduction in the early weeks postsurgery

because rejection episodes tend to be more frequent during this period. A much more frequent schedule of NMR examinations and biopsies would be needed to test this hypothesis. Nevertheless, the occurrence of reductions in the high energy phosphate metabolism of a majority of transplant patients is a concern meriting further study.

4.3 Coronary Artery Disease

4.3.1 Myocardial Infarction

Published papers to date show no significant alterations in resting myocardial PCr/ATP ratios in myocardial infarction.^{17,40,46,55} Two reports do show significantly reduced resting PCr/ATP in patients with infarction and irreversible ²⁰¹Tl defects by radionuclide imaging.^{31,42} It is unclear whether other factors such as heart failure and/or cardiomyopathy may play a role in these patients and could explain the different findings.¹⁰ In recent anterior myocardial infarction, significant elevations in P_i levels can be detected within the first week or so after onset,¹⁷ which is consistent with canine ³¹P NMR studies showing elevated P_i levels persisting for several days postcoronary occlusion, as a byproduct of PCr and ATP consumption.⁷² Biochemical analyses of animal hearts also show that essentially all the ATP and PCr is depleted within the first few hours of ischemic injury that results in cell death.⁶ Thus again, as dead cells can contribute no high energy phosphates, it is likely that the normal resting PCr/ATP ratios derive from a mixture of metabolically normal tissue, scar tissue and, possibly, jeopardized myocardium adjacent to, or interspersed with, the infarction. Accordingly the infarction itself may best be characterized by the absence of any contribution to the spectrum.

Evidence for the possible use of ³¹P NMR for assessing myocardial viability, is provided by a study of 29 patients with recent myocardial infarction.⁴⁶ This revealed no changes in PCr/ATP ratios in patients with myocardial stunning after reperfusion, suggesting that relative levels of high-energy phosphates are not depleted in stunned human myocardium.

There is now ³¹P NMR evidence that the metabolite concentrations are reduced in infarction itself.^{31,55} This includes the observation of a significant negative correlation between ATP levels and the size of perfusion deficits in the heart, as quantified by thallium ²⁰¹Tl radionuclide imaging,⁵⁵ and reductions in [PCr] and [ATP] in patients with fixed ²⁰¹Tl defects compared with those with reversible defects.³¹ Concentration measurements made by ³¹P NMR must be treated cautiously, however, since the tissue volume present in the voxel may be reduced by any wall thinning that occurs after infarction. This may partially offset the signal loss due to infarction, depending on how tissue volume is accounted for in the concentration measurements. Nevertheless, the observations^{31,55} are consistent with a model for infarction wherein the myocardial PCr and ATP levels are reduced in the heart spectrum in proportion to the volume of infarcted tissue that intersects the voxel.¹⁰

Reductions of about 60% in myocardial [CR] can also be detected with water-referenced ¹H NMR in patients with myocardial infarction.⁴ The results are consistent with animal studies and the concept of metabolic depletion in infarction. Because the resolution and sensitivity are better with ¹H NMR than with ³¹P NMR (and because the CR resonance has three

protons compared with the single phosphate group of PCr), ^1H NMR could provide a useful metabolic means for distinguishing healthy from infarcted nonviable myocardium.

4.3.2 Myocardial Ischemia

In patients with ischemic heart disease involving severe stenosis of the anterior vessels the resting anterior myocardial PCr/ATP ratio is normal,⁴⁰ or nearly so.⁵ To observe metabolic change corresponding to reversible ischemia, safe and effective stress protocols that can be performed in the NMR magnet for the duration of a localized ^{31}P NMR examination are necessary. Three types of stress have been tried: aerobic exercise involving the lifting of weights with the legs;⁷³ an isometric exercise, performed, for example, with a handgrip dynamometer;^{5,42} and stress induced by pharmaceutical agents such as dobutamine.^{45,63} The increase in cardiac work-load indexed by the heart rate–blood pressure product in these protocols is about 70% for an aerobic leg exercise lifting 5 kg weights;⁷³ about 30–35% with the isometric hand-grip exercise at 30% of the subjects maximum force;⁵ and up to 130% (2.3-fold) with dobutamine infusion.^{45,63} While producing a lesser increase in cardiac work, the isometric exercise protocol can produce reflex coronary vasoconstriction in stenosed vessels. It also minimizes motion problems during NMR acquisition compared with aerobic exercise, and, in addition, produces vasoconstriction in patients with critical coronary disease.⁵ It is also well tolerated by CAD patients, and can be immediately terminated should complications arise.

Phosphorus-31 NMR exercise stress testing of healthy volunteers who are free of significant CAD appears to elicit no significant alterations in anterior myocardial PCr/ATP ratios, with a 30–70% increase in rate–pressure product.^{5,73} Dobutamine stress testing at 230% rate–pressure product produced no significant change in seven normal controls, although a recent study of 20 healthy volunteers elicited a statistically significant 14% reduction in myocardial PCr/ATP at a 300% rate–pressure product.⁴⁵

There are two papers reporting ^{31}P findings from isometric hand-grip stress testing of patients with documented anterior wall ischemia.^{5,42} In the first hand-grip exercise, the PCr/ATP ratio decreased by 37% in a group of 16 patients with severe anterior stenoses (Figure 3).⁵ After exercise, metabolite ratios recovered to near-normal, pre-exercise values. Eleven healthy control subjects, and nine patients with nonischemic heart disease (cardiomyopathy or valve disease) exhibited no PCr/ATP changes during the same exercise, suggesting that the stress-induced changes in PCr/ATP are specific to CAD. Five CAD patients underwent repeat ^{31}P NMR stress-testing after successful revascularization therapy.⁵ Prior to therapy, stress provoked a 33% decrease in PCr/ATP in these patients, as in the larger group. Exercise stress testing performed posttherapy produced no change, indicating that the metabolic abnormality resolves with successful clinical outcome.

The second report found a similar 40% decrease in the PCr/ATP ratio in patients with reversible anterior wall ischemia that was confirmed by exercise ^{201}Tl radionuclide imaging.⁴² Twelve patients with fixed ^{201}Tl defects indicative of myocardial infarction, as well as normal controls, exhibited no exercise induced PCr/ATP changes. This, and the observation that dobutamine stress testing induced no significant reduction in myocardial PCr/ATP, on average, in patients with DCM,⁶³

Figure 3 Transient changes in the anterior myocardial PCr/ATP ratio in (a) control subjects free of CAD, and (b) patients with CAD involving the anterior wall, in response to continuous isometric handgrip exercise at 30% of the subjects maximum force.⁵ Error bars show means $\pm$ SD. (Reproduced by permission of *New England Journal of Medicine* from Weiss et al.⁵)

is further evidence that the stress-induced changes may be specific for ischemia.

Present ^{31}P NMR studies are limited to the anterior wall. Whether ^{31}P NMR stress testing might play a role in the evaluation of ischemia in the clinic may depend in part on extending ^{31}P NMR to other regions of the heart, which will necessitate further improvements in sensitivity such as those afforded by NOE and phased array detection coils. Comparative studies of sensitivity relative to existing clinical modalities would then be needed.

4.3.3 Cardiac Model

In summary, the ^{31}P studies of myocardial infarction and reversible ischemia suggest a model in which the cardiac spectrum from a voxel comprises of up to four components: (i) myocardium either with an essentially normal resting PCr/ATP ratio or, possibly, a reduced resting PCr/ATP ratio due to complications arising from chronic infarction such as heart failure or cardiomyopathy; (ii) jeopardized myocardium whose PCr/ATP ratio decreases with stress testing; (iii) scar tissue with lower ATP and PCr concentrations; and (iv) infarcted myocar-

Figure 4 Model for the observed cardiac spectrum as the integral of four potentially distinguishable components: (i) myocardium either with an essentially normal resting PCr/ATP or, possibly, a reduced resting PCr/ATP ratio associated with heart failure; (ii) jeopardized myocardium, possibly only distinguishable from normal or failing heart by stress testing; (iii) a mixture of infarction with no PCr or ATP but perhaps some residual P_i shortly after infarction, and scar tissue, presumably with lower ATP and PCr concentrations; and (iv) contaminating signal from blood¹⁰

dium with no PCr, ATP, or CR but possibly some residual P_i persisting several days after infarction. Appropriate choice of the ^{31}P or ^1H NMR protocols may resolve these components: measurements of the metabolite concentrations at rest may index the fraction of scar tissue and infarction present in a selected volume, while jeopardized myocardium may be indexed by stress testing (Figure 4).¹⁰

Research specialties: in vivo NMR imaging, localized spectroscopy, tissue relaxation times, MRI, human cardiac NMR spectroscopy.

Brain Infection and Degenerative Disease Studied by Proton MRS

Robert E. Lenkinski, Dolores López-Villegas,
and Supoch Tunlayadechanont

University of Pennsylvania, Philadelphia, PA, USA

1 INFECTIONS

1.1 Creutzfeldt–Jakob Disease (CJD)

Bruhn et al.¹ showed in an initial case report of CJD that there was significant loss of *N*-acetylaspartate (NAA) in both white matter (40%) and gray matter (30%). The level of inositol, presumably myo-inositol (MI), was higher than normal (30%) in white matter. The conventional magnetic resonance (MRI) images of this patient showed only mild cortical atrophy and hyperintensities in the lentiform nuclei. These authors suggested that proton MRS might be useful in the early detection of CJD.

Graham et al.² have studied two patients with biopsy proven CJD using in vivo MRS. High-resolution NMR spectroscopy was also carried out on an extract of a biopsy specimen of a third patient with CJD.² These NMR results were compared with neuronal cell counts. Marked decreases in the levels of NAA (detected in vivo) were observed at later stages of disease in two patients. However in the early stages of CJD smaller decreases were observed (15% and 27%) in the level of NAA. The NMR spectrum obtained from the biopsy sample taken from a third patient showed little or no reduction in the levels of metabolites. In contrast with the previous case report of Bruhn et al.¹ Graham et al. suggested that there should be little or no change in the levels of metabolites in the early stages of CJD. This suggestion was supported by referring to the known pathophysiology of CJD which indicates that neurons are lost relatively late in the disease process.

1.2 Herpes Simplex Encephalitis (HSE)

Menon et al.³ showed in an early case report that the ratio of NAA to choline (NAA/Cho) was reduced in an 11 year old boy. This reduction observed at eight weeks after the onset of symptoms was found to be unaltered on follow-up examination (16 weeks), indicating that there was no progressive neuronal loss. This observation was consistent with the clinical evaluation of the patient.

As part of an MRI study of HSE involving eight patients, Demaerel et al.⁴ obtained proton spectra from two patients with HSE. The proton spectra from one of the HSE subjects are shown in Figure 1.

Note the reduction in NAA observed in the affected region as compared with the contralateral temporal lobe. There is also a significant amount of lactate observed. The authors interpret

the observation of lactate to indicate the presence of an infarct.

1.3 Intracranial Tuberculomas

Gupta et al.⁵ have reported the results of localized proton MRS carried out on two patients with intracranial tuberculo-

Figure 1 Solvent-suppressed proton spectra obtained using the STEAM sequence at 1.5 T ($TR = 3000$ ms, $TE = 270$ ms) from a 27 cm^3 voxel located at (a) the left and (b) the right temporal lobe. Each spectrum is the sum of 256 acquisitions. Reproduced with permission from Demaerel et al.⁴

Figure 2 Solvent-suppressed proton spectra obtained using the STEAM sequence at 2.0 T ($TR = 5000$ ms, $TE = 20$ ms) from an 8 cm^3 voxel located (a) in a tuberculoma and (b) in a contralateral normal brain. Each spectrum is the sum of 128 acquisitions. Reproduced with permission from Gupta et al.⁵

mas. A large resonance was observed between 0.7–1.6 ppm (see Figure 2) which was assigned to the $(\text{CH}_2)_n$ group of saturated fatty acids. The presence of this peak was attributed to the large lipid fraction present in the tubercule bacillus.

1.4 Human Immunodeficiency Virus (HIV) Infection

Menon et al.⁶ reported the first spectroscopic study of the brains in patients infected by Human Immunodeficiency Virus

(HIV). The authors examined two patients with AIDS [Centers for Disease Control classification (CDC) Group IV] and evidence of focal CNS pathology. A multiple-echo spectroscopy acquisition (MESA) sequence with a TR of 2000 ms and TE of 270 ms was employed. The spectra were collected from a 64 cm^3 voxel in the right parietal region. Although these patients had abnormal MRI, the spectra were taken in areas of normal appearing white matter. In both cases the spectra showed a marked reduction in the ratio of NAA/Cho and NAA/creatine (NAA/Cr) when compared with control subjects. The authors proposed that the spectral changes in these regions which appear normal on MRI may be attributed to other causes but is most likely to be due to primary HIV infection. The authors first demonstrated the ability of proton MRS to detect brain abnormalities in HIV-infected patients at a stage when it is undetectable by imaging and proposed a possible role for the early selection of patients for treatment with antiviral drugs.

The same group examined 11 patients with HIV infection and varying stages of AIDS dementia complex (ADC) (actually known as HIV-1-associated cognitive/motor complex).⁷ In this study, patients with pathology seen on MR imaging that could not be directly attributed to HIV infection of the brain were excluded from the study. Spectra were obtained from 27 to 64 cm^3 voxels in the parieto-temporal regions using the same sequence as in the previous study. Spectra from patients with moderate (Stage 2) to severe ADC (Stage 3), when compared with spectra from normal volunteers, exhibited significant reductions in NAA/Cr ratio and a tendency to increased Cho/Cr ratio, although this last trend did not reach statistical significance. Spectra from patients with no ADC (Stage 0) or early ADC (Stage 1) were not significantly different from normal volunteers (see Figures 3 and 4).

Many of the patients in this study exhibited abnormalities on MRI, but apart from the presence of atrophy, which was seen in all of the patients with moderate to severe ADC, MRI did not seem to discriminate between patients with and without ADC. The authors concluded that although the NAA/Cr ratio may not be an early or sensitive marker of ADC, it may be relatively specific since all of the patients with significantly low values of this ratio had a clinical diagnosis of ADC.

Meyerhoff et al.⁸ examined 14 HIV seropositive patients, 10 with varying degrees of cognitive impairment and four who were cognitively asymptomatic. Spectra were obtained from nine 2.5 cm^3 volumes in the centrum semiovale and the mesial cortex in each patient. Significantly reduced NAA/Cho and NAA/Cr ratios were observed in cognitively impaired subjects versus normal controls, without significant regional differences between the voxels studied. No significant differences were found between groups with cognitive impairment and asymptomatic groups or between asymptomatic and control groups.

This study reported diffuse reductions in NAA in individuals with cognitive impairment due to HIV. Contrary to previous studies, most of the patients in this study had normal appearing MRI (80%) suggesting that proton MRS is more sensitive than imaging in assessing the effects of HIV infection on the brain.

Jarvik et al.⁹ examined 11 HIV seropositive patients without clinical, radiological, or laboratory evidence of CNS infections other than HIV. Proton spectra were acquired with the stimulated echo acquisition mode (STEAM), TR of 2000 ms, TE of

Figure 3 Solvent-suppressed proton spectra obtained from a 27 cm³ voxel located in the parietal lobe from a healthy volunteer and three patients with HIV infection. The spectra were obtained with a double-echo sequence, $TR = 2000$ ms, $TE = 270$ ms. Each spectrum is the sum of 128 acquisitions. The spectra are displayed with creatine scaled similarly. The spectra are from (a) a healthy volunteer, (b) a patient with ADC Stage 0, (c) a patient with ADC Stage 1, and (d) a patient with ADC Stage 3. Reproduced with permission from Menon et al.⁷

19 ms, and TM of 10.6 ms. Voxels of 3.4–8 cm³ were chosen to cover areas of abnormal white matter signal intensity if present, or centrum semiovale if the white matter appeared normal at imaging. Analysis of the images showed that there was a significant difference between the patients and control subjects with respect to atrophy, although no significant difference was found between the appearance of the white matter in patients and control subjects. Analysis of the spectra showed that the NAA/Cr ratio was significantly lower and Cho/Cr and marker peak/Cr ratios significantly higher in patients as compared with control subject. The authors calculated an aggregate score that

Figure 4 A comparison of the NAA/Cr ratios in normals and patients with different stages of ADC. The bars represent 1 SD. The NAA/Cr ratio is significantly reduced in the ADC Stage 2 and 3 as compared with any of the other groups ($P < 0.05$). Reproduced with permission from Menon et al.⁷

combined these three ratios. This aggregate score proved to be a good discriminator between the patient and control populations ($P = 0.001$) (see Figure 5).

The aggregate scores were abnormal (>2 SDs from the mean of the control subjects) in 13 out of 15 patient spectra (87%), while 8 out of 11 patients (73%) had abnormal MR images. Moreover, only one out of 10 control spectra (10%) was abnormal while four out of 11 controls (36%) had abnormal imaging. These results suggested that MRS may be more sensitive and specific than MR imaging in detecting CNS involvement in HIV-infected patients.

Chong et al.¹⁰ reported the largest study in which proton MRS was performed in 103 HIV seropositive patients and 23 control subjects. Spectra were collected from an 8 cm³ voxel placed in a normal parieto-occipital region of the brain using a 90°, 180°, 180° spin echo sequence (PRESS), TR of 1600 ms and TE of 135 ms. In the first part of the study, the spectra of HIV seropositive patients were compared and correlated with clinical, immunologic, and radiologic measures of HIV infection. A significant reduction in the NAA/Cr ratio was seen in patients with late-stage disease (CDC Group IV). The NAA/Cr and NAA/Cho ratios were also reduced in patients with CD4 counts <200 mm⁻³ and in patients with neurologic signs. Significant increases in Cho/Cr ratios were seen in patients with low CD4 counts and abnormal MR images. Reduced NAA ratios correlated with diffuse but not focal MR imaging abnormalities. In the second part of the study, the authors evaluated the utility of combining the results of MR imaging and spectroscopy, finding that the combination of both modalities provides closer relationships to clinical and immunologic measures of disease than either modality alone. Moreover, abnormal spectra correlated more with abnormal neurologic finding than did abnormal MR images, suggesting that spec-

Figure 5 Aggregate spectral scores (Cr/NAA + Cho/Cr + marker/Cr) obtained from normal volunteers and patients with HIV infection. The mean and 1 SD lines are indicated. Note the almost complete separation between the two groups. See Jarvik et al. for experimental details⁹

troscopy may be sensitive to changes in cerebral chemistry that are clinically relevant and are not apparent on MR images.

The same authors¹¹ studied 43 HIV seropositive patients, including 26 who had clinical or radiologic evidence of late-stage disease (CDC Group IV) and 17 in the early stages of infection (CDC Groups II and III). Using the same sequence as described above, spectra were obtained from a 8 cm³ voxel placed in a normal parieto-occipital region of the brain. When patients grouped by different criteria were compared, a significant reduction in the NAA/(NAA + Cho + Cr) ratio was found in patients in the late stage of the disease as compared with those in early stage disease. This ratio was lower in patients with HIV-1-associated cognitive/motor complex as compared with patients who were neurologically healthy. Also this ratio was decreased in patients with abnormal MR images (diffuse white matter abnormalities) as compared with those with normal appearing white matter. When patients were compared with healthy control subjects, the NAA/(NAA + Cho + Cr) ratios were significantly higher in control subjects than in CDC Group II and III patients and also significantly higher than in all seropositive patients with normal MR imaging. The authors noted, however, that the control group was younger and so these last results may be influenced by the expected decrease in NAA levels which parallel neuronal loss with age. The authors reported the first follow-up spectroscopic study performed in 15 patients between three and eight months after their initial studies. A significant reduction in the NAA/(NAA + Cho + Cr) ratio was observed at follow-up study when compared with the initial examinations.

The results of all of the MRS studies of HIV infection are summarized in Table 1.

A common finding in all of the studies on HIV infection of the brain is the reduced level of NAA. Although NAA, which resonates at 2.0 ppm, is the most prominent resonance in the brain proton spectrum, its precise biochemical function is not clear. It has been suggested that NAA is involved in the regulation of lipid synthesis, the regulation of protein synthesis, or as a storage buffer for aspartate. Since NAA is largely confined to neurons it has been proposed as a neuronal marker. Hence, decreases in the level of NAA may be interpreted as a sign of neuronal loss or injury. This finding is consistent with the pathologic evidence of neuronal loss reported in HIV infected patients. Another common finding, although not present in all of the studies, is the increase in Cho/Cr ratio. Choline, which resonates at 3.2 ppm, is an important precursor of cell membrane synthesis and is often found to be elevated in tissues that are rapidly regenerating or undergoing membrane disruption. The significance of the elevation in Cho/Cr ratio remains uncertain. A possible interpretation for this increase in HIV infected patients is that the increased Cho may not directly arise from changes in neurons but may result from metabolic alterations in glial or inflammatory cells.⁷ An alternative interpretation is that the increase in Cho/Cr ratio combined with the increase in marker/Cr ratio, also observed in these patients, may reflect myelin damage.⁹ Choline phosphoglycerides contribute 11.2% of myelin lipids, with phosphatidylcholine being the most abundant. Therefore, as myelin damage occurs, free choline may be released increasing the choline resonance detected by MRS. The 'marker peak' region between 2.1–2.6 ppm may be a combination of nonspecific amino acids and possibly myelin catabolites which may increase with myelin breakdown. Both explanations for the increase in Cho/Cr ratio are consistent with the neuropathologic finding of inflammatory infiltrates and white matter abnormalities in the brain of HIV infected patients. An alternative explanation proposed for the increase in this ratio is the decrease in Cr resonance.¹⁰ This resonance at 3.0 ppm reflects the concentration of the total creatine pool (PCr and Cr). The level of this peak remains stable under many conditions in the brain. The decrease in creatine pool may indicate impairment of cellular metabolism in the brain of these patients and is supported by the decrease in PCr peak observed in phosphorus MRS studies.

Abnormal proton spectra may be found in normal-appearing white matter on imaging, suggesting that MRS may be more sensitive than MRI in detecting CNS involvement in HIV infected patients. Moreover, MRS seems to be a better discriminator between the patient and control populations than MRI, suggesting that MRS may be also more specific. When individuals displaying different manifestations of illness were compared, the abnormalities in the spectra correlated with the presence and the severity of the cognitive impairment and with clinical and immunologic measures of late-stage disease. These findings suggest that MRS may serve as an indicator of the degree of CNS involvement. Therefore, MRS may serve to monitor the course of disease progression and may have a prognostic role regarding CNS involvement. This modality may provide a sensitive method for the early detection of HIV migration to the CNS. Finally, MRS can be employed in longitudinal studies to monitor the response to therapy and thus may lead to individual optimized treatment effectiveness.

Table 1 A Summary of the Proton MRS Findings in HIV infection

Study	Patients (p) Controls (c)	Stage ^a		Clinical evidence of CNS involvement		MRI findings ^c		MRS sequence and parameters	MRS findings	Groups statistically distinguished by MRS

		early-stage	17	(HIV-1-associated cognitive/motor complex) no cogn. imp.	6 14	normal	34	<i>V</i> = 8 cm ³ normal parieto- occipital region		

^aStage: late stage refers to CDC Group IV, early stage to CDC Groups II and III. ^bADC refers to the aids dementia complex, actually known as HIV-1-associated cognitive/motor complex. Cogn. imp. is an abbreviation for cognitive impairment. ^cAbnormal MRI: abnormalities were either GM atrophy or WM signal changes. ^dNot all of the subjects had complete neurological examinations. ^eThe remaining patients (33) were excluded because they exhibited focal lesions on MRI.

Figure 6 The variation in the mol% of glutamate with the mol% of NAA in the NMR spectra of extracts of brain samples from patients with AD. See Klunk et al. for experimental details¹²

2 DEGENERATIVE DISEASES

2.1 Alzheimer's Disease (AD)

2.1.1 In Vitro Studies of AD

Klunk et al.¹² determined the mole ratios of several amino acid metabolites in perchloric extracts of 12 AD and five control brain samples from either the junction of the superior and middle frontal cortex or the superior temporal cortex. NAA and γ -aminobutyric acid (GABA) were found to be lower in AD. The NAA levels also had a negative correlation to the numbers of senile plaques (SP) and neurofibrillary tangles (NFT). As shown in Figure 6, glutamate levels were greater in AD and had an inverse correlation with NAA levels. The authors suggested that these findings applied to in vivo studies and reflected neuronal loss, while the remaining neurons were exposed to the potentially excitotoxic effect of glutamate.

2.1.2 In Vivo Studies of AD

Miller et al.¹³ used the STEAM sequence, at field strength of 1.5 T and TE 30 ms, to acquire proton spectra from 10–15 ml voxels in white matter located in the parietal area (WM) and gray matter in the occipital cortex (GM). Summed spectra are shown in Figure 7. They reported an increased myoinositol/creatine (MI/Cr) ratio, which suggested abnormalities in the inositol polyphosphate messenger pathway, and reduced NAA/Cr in AD compared to controls. The difference in NAA/Cr level was small but statistically significant in both WM and GM voxels. The increase in MI/Cr was more prominent, especially in GM. However, there was no correlation between the severity of the disease and spectroscopic findings.

Shiino et al.¹⁴ studied a patient group ($n = 9$) with primary degenerative dementia (PDD) which included seven patients with probable AD, three normal pressure hydrocephalus (NPH), and healthy controls. The DRY STEAM technique was applied with a TR of 2500 ms, TE of 19 ms, and TM of 5.7 ms. The NAA/Cr was significantly reduced in patients with PDD,

Figure 7 Representative summed solvent-suppressed proton spectra obtained using the STEAM sequence ($TR = 1500$ ms, $TE = 30$ ms) from (a) normal volunteers ($n = 8$) and (b) patients with AD ($n = 8$). Reproduced with permission from Miller et al.¹³

with no significant brain atrophy or reduction in regional blood flow detected by SPECT. There was no reduction of NAA/Cr in PH. These authors concluded that, in the appropriate clinical setting, proton MRS was a useful measure for the early detection and study of PDD (see Figure 8).

Figure 8 A correlation plot of NAA/Cr versus age. Normals are designated by filled circles. Patients with primary degenerative dementia (PDD) are designated with open circles and patients with normal pressure hydrocephalus are designated by triangles. See Shiino et al.¹⁴ for experimental details

2.2 Parkinson's Disease (PD)

Shiino et al.¹⁴ examined two patients with PD using proton MRS. Spectra were acquired from a 27 cm³ voxel located in the insular area of the brain. A decrease in the NAA/Cr ratio was observed in the two patients with PD when compared with control subjects. Even though the mean age in the control group was lower, the authors observed that there were no age-related changes in the mean area ratio of NAA/Cr in this group. Both PD patients examined in this study exhibited marked atrophy on MRI, and since the spectra were obtained from voxels placed in the insular area these results should be interpreted with caution.

2.3 Huntington's Disease (HD)

Jenkins et al.¹⁵ reported the results of a proton MRS study in a series of HD patients. Sixteen patients with clinical signs of definite HD and confirmed family history and two individuals without neurologic affection but with linked DNA markers, indicating a high probability to have inherited the HD gene, were examined. Proton spectroscopy was performed using a STEAM sequence with *TR* of 2000 ms, *TE* of 272 ms, and *TM* of 10 ms. Spectra were collected from a 15.6 cm³ voxel placed over the visual cortex and from a 5.4–20 cm³ voxel placed in basal ganglia. A 5 inch surface coil was used to study the occipital cortex and the quadrature head coil was used for studies of the basal ganglia. Elevated lactate levels were observed in the occipital cortex in all of the symptomatic patients when compared with normal controls. The lactate level correlated with the duration of illness. Lactate levels were normal in the two asymptomatic subjects with high probability of having the HD gene. In the basal ganglia, the levels of NAA were decreased and the levels of Cho elevated relative to creatine. Several patients also showed elevated lactate levels in the basal ganglia.

The authors suggested that the increase in lactate may be explained by a defect in oxidative phosphorylation in HD. This possibility is supported by biochemical studies that have reported reduced mitochondrial enzyme activity in HD patients, and ultrastructural studies that have shown abnormalities in the mitochondria of these patients. The reduced NAA and increased Cho were interpreted in these patients as resulting from neuronal loss and gliosis. The authors suggested that lactate likely precedes neuronal death and that this may be the explanation for the more variable lactate elevation in the basal ganglia where evidence of more neuronal loss and gliosis was found. On this basis, they proposed that the elevated lactate may provide a simple marker to monitor the progression of the disease and possible therapies for HD patients.

High-resolution proton MRS was employed by Nicoli et al.¹⁶ to study CSF and serum metabolic samples obtained from patients with HD. Serum and CSF samples were collected from 11 patients suffering HD and 12 reference patients suffering miscellaneous neurological diseases. A significant increase in the pyruvate concentration in CSF was found in patients with HD. This finding may be explained by the decrease of pyruvate-dehydrogenase and Krebs's cycle enzyme activity observed in HD patients. This observation is consistent, as was the finding of elevated lactate reported by Jenkins et al.,¹⁵ with

the hypothesis of the existence of a defect in oxidative phosphorylation present in this disease.

1 INTRODUCTION

Magnetic resonance spectroscopy (MRS) was first introduced into pediatrics in the early 1980s as a method for the noninvasive investigation of perinatal brain injury.¹ This injury is often due to cerebral periventricular hemorrhage (PVH) in preterm infants (born before 37 weeks of gestation) or to hypoxia-ischemia in both preterm and term infants. It is responsible for permanent neurodevelopmental impairments in about 10% of disabled children of school age. In the 1970s, X-ray computerized tomography (CT) and, more especially, ultrasound imaging using portable equipment at the cotside, were found to be useful for investigating the incidence, pathogenesis, and prognostic significance of PVH, but long-term follow-up studies indicated that hypoxia-ischemia, often causing periventricular leukomalacia, was a more important cause than PVH of permanent disabilities in preterm infants.² In term infants, hypoxia-ischemia was the mechanism by which 'birth asphyxia' (critically impaired gas exchange during labor) damaged the brain. Overall, hypoxia-ischemia turned out to be the most prevalent cause of serious perinatal brain injury, so there was an obvious need for noninvasive investigation of cerebral oxidative metabolism, and hence of the pathogenesis and evolution of hypoxic-ischemic brain injury. MRS was thought to provide a suitable, noninvasive, method for obtaining biochemical information from the otherwise inaccessible neonatal brain.³⁻⁵

In the early 1980s, ³¹P MRS had already been used to investigate oxidative metabolism in human skeletal muscle in vivo and the first in vivo spectra had been obtained from mammalian brain.⁶ However, studies of newborn infants had to await the development of superconducting magnets with a sufficiently wide bore (approximately 20 cm) and a high enough field strength for spectroscopic work. These magnets (intended primarily for studies of human limb muscles), became available in the early 1980s, and investigations of the brain in newborn infants started shortly thereafter.^{1,7} The first in vivo spectra from the human brain were obtained from a preterm baby at University College London in 1982 using the ³¹P nucleus.¹ It rapidly became clear that metabolites involved in energy metabolism [e.g. adenosine triphosphate (ATP), phosphocreatine (PCr), and inorganic phosphate (Pi)] as well as those related to more fixed cellular components, namely phosphomonoesters (PMEs) and phosphodiester (PDEs), were easily detected. Intracellular pH (pH_i) could

also be measured. Obvious spectral abnormalities were soon found in the brains of infants with hypoxic ischemic injury.^{1,7} ³¹P spectra have also been obtained from the brains of older children and developmental changes have been elucidated. In addition, ¹H spectra have demonstrated products of anaerobic glycolysis such as lactate (Lac), various amino acids (e.g. glutamate and glutamine), and other brain metabolites, including those containing choline (Cho; related to membrane metabolism) and *N*-acetylaspartate (NAA; a putative neuronal marker). Localization of spectra to specific regions of the brain was initially crude, relying solely on the sensitive volume of a surface coil. Recently, techniques have been developed that enable spectra to be acquired from well defined volumes of tissue, so deeper and focal lesions can be investigated.

The purposes of this article are to summarize the methods used for MRS of the brain in infants and children, to describe what has been learnt about normal brain development, and then to consider the role of MRS, particularly in the investigation of hypoxic ischemic brain injury.

2 PATIENT MANAGEMENT

MRS studies of the brains of infants and children are safe provided that current recommendations are observed,⁸ though the requirements for physiological support and monitoring are often much greater than for adults.

Newborn infants, who may be in an unstable condition, have to be conveyed and studied in a specially designed transport incubator incorporating a nonmagnetic, cylindrical pod that encloses the baby and is suitable for insertion into the magnet. Conventional facilities for temperature control, monitoring, and mechanical ventilation are provided.^{9,10} Monitoring of heart rate [by electrocardiogram (ECG) or ultrasound Doppler flow], blood pressure, arterial oxygen saturation (by pulse oximetry), end-tidal CO₂, transcutaneous pO₂ and pCO₂, and body temperature (by skin and/or rectal sensors) should be available. Intravenous infusions may have to be provided. Newborn infants can often be studied satisfactorily whilst naturally asleep following a feed. However, sedation with, for example, chloral hydrate is often required for studies of older children. Especially for the newborn, the head must be gently immobilized during studies using, for example, a polythene bag containing expanded polystyrene beads and which can be evacuated. Clinical apparatus must be carefully designed to take into account the large range of size of infants and children. It is important that the data acquisition protocol is such that useful information can be obtained even if small movements take place.

Interactions between magnetic fields (both static and transient) and the pulsed rf, and the monitoring equipment needed for patient care, require consideration. Some sensors contain ferromagnetic components that can impair the homogeneity of the magnetic field. Many manufacturers of monitoring equipment can supply special magnetic resonance compatible devices. Alternatively, it may be possible to position ferromagnetic components so that their effects are unimportant. Some sensors may pick up rf interference, thereby decreasing the signal-to-noise ratio and transient rf and pulsed magnetic fields may overload ECG and other devices. The accidental formation

of conductive loops by sensor cables must be avoided. This is in order to eliminate the risk of burns that could be caused if currents are induced by transient rf and pulsed gradient fields.¹¹ Microprocessors, included in many newer monitors, emit rf interference and thus special rf Faraday shields and filters are required. Also, the spectrometer must be safe in the presence of the high inspired oxygen concentrations needed by some patients. Probes (rf) must be tested to ensure that transmitter pulses do not cause arcing; they must be in sealed containers which, as a further precaution, can be flushed with a relatively inert gas such as N₂.

3 DATA ACQUISITION

Using surface coils with diameters in the range 5–7 cm and without further localization techniques, good quality ³¹P spectra can be obtained from 10–50 mL of the cerebral cortex of the newborn infant. These spectra have very little contamination from other tissues since skin and fat contain little ³¹P, cranial muscle is sparse, and the cranial bones are poorly mineralized and have relatively immobile ³¹P nuclei. For basic studies of the normal brain and abnormalities associated with nonfocal brain injury, valuable information has been obtained without better spectroscopic localization. However, the sensitive volume provided solely by a surface coil is not well defined. For investigations of focal metabolism, particularly deep in the brain, and in older infants and children who have better developed cranial musculature, and also for ¹H studies, in which fat contamination can be a problem, spectroscopic localization techniques are essential. Many volume localization methods exist which have been used successfully for studies of infants and children. These techniques all employ pulsed magnetic field gradients to obtain low-contamination spectra from a well defined voxel positioned with reference to MRI scout images. In these multipulse techniques, rf power is higher than for 'single pulse' surface coil methods and consequently greater attention to safety is mandatory.

Image-selected in vivo spectroscopy (ISIS; see *Single Voxel Whole Body Phosphorus MRS*)¹² has been used for ³¹P studies of the developing brain¹³ and, in order to combine MRI with localized ³¹P MRS, double-tunable probes dedicated to the examination of children's brains have been developed.¹⁴ For neonatal applications, standard probeheads are usually too large and give poor signal-to-noise ratio with the tiny voxels (about 1 mL) often necessary when studying the smaller anatomy. Localized ¹H spectra from infants and older children have been acquired using both the point resolved spectroscopy (PRESS) and stimulated echo amplitude mode (STEAM) techniques (see *Single Voxel Localized Proton NMR Spectroscopy of Human Brain In Vivo*).¹⁵ MR spectroscopic imaging¹⁶ (see *Chemical Shift Imaging*) has not been as widely applied as the single voxel methods. Absolute concentrations (i.e. in millimoles per kilogram wet weight, or millimoles per liter) of ³¹P metabolites in developing brain have been estimated both by PRESS with brain water as an internal reference,¹⁷ and by ISIS with an external reference.¹⁸ The absolute concentrations of ¹H metabolites are more difficult to estimate, due largely to the dependences of peak areas on T₂ relaxation and, in the case of multiplets, on phase modulation. However, some information about developmental changes has been acquired using

an external reference¹⁹ or brain water as an internal reference.^{17,20}

4 NORMAL BRAIN DEVELOPMENT IN INFANTS AND CHILDREN

Information about the relative and absolute concentrations of metabolites detectable by ³¹P and ¹H MRS in the developing human brain has been acquired at several centers worldwide with good agreement of results.

4.1 The Neonatal Brain

The major ³¹P energy related resonances in spectra from skeletal muscle had been securely assigned when the first studies of the neonatal brain were carried out. Peaks attributable to γ -, α -, and β -nucleotide triphosphate (NTP), PCr, and Pi, all of which are involved in energy metabolism, were also detected in the brains of newborn infants (see Figure 1). Magnesium complexed ATP is the main contributor to cerebral NTP, with guanosine, uridine, and cytidine triphosphates making up about a quarter of the remaining NTP pool;²¹ the γ - and α -NTP resonances have small contributions from nucleotide diphosphates; and an often unresolved nicotinamide adenine dinucleotide (NAD + NADH) quartet resonates on the right-hand shoulder of α -NTP.²² Within the physiological range, the PCr resonant frequency is independent of both pH_i (it only shifts significantly at very low pH) and metal ion concentration; it is often used as a chemical shift reference (assigned as 0 ppm).

Only a single Pi resonance (peak 2) is visible in the ³¹P spectra shown in Figure 1. Its chemical shift relative to PCr (δ_{Pi}) depends strongly on the concentration ratio of its acidic and basic species ($\text{p}K_{\text{a}} \approx 6.8$) and hence pH_i can be estimated from the Henderson–Hasselbalch equation:²³

$$\text{pH}_i = 6.77 + \log_{10}[(\delta_{\text{Pi}} - 3.29)/(5.68 - \delta_{\text{Pi}})] \quad (1)$$

Estimation of pH_i is accurate to about 0.1 pH units. At high field strengths (≥ 4.7 T), the Pi peak can often be resolved into extra- and intracellular²⁴ and perhaps also mitochondrial components,²⁵ implying the presence of compartments of different pH.

When the first ³¹P spectra were acquired from the neonatal brain, problems arose with the interpretation and assignment of prominent resonances other than those particularly involved in energy metabolism. The PME and the moderately broad, unresolved PDE peaks were both surprisingly large, and surface coil spectra were superimposed on a broad hump [see Figure 1(c)]. Chromatography and ³¹P and ¹H MRS of extracts of neonatal mammalian brain have identified phosphoethanolamine (PEt) as the main contributor to the PME peak²⁶ which also includes phosphocholine (PC) and several smaller resonances, due for example to phosphoserine and phosphoinositol.²² These PMEs are involved in phospholipid metabolism, including the synthesis of myelin.

The moderately broad resonance at about 2.9 ppm [see Figures 1(a) and 1(b), peak 3] is largely attributable to cross linked PDEs in membrane bilayer phospholipids and also to a small pool of mobile phospholipid breakdown products

Figure 1 ^{31}P spectra acquired from the temporo-parietal cortex of (a) a preterm infant of gestational plus postnatal age (GPA) 31 weeks; (b) an infant born and studied at full term. Pi is relatively smaller and PCr larger in spectrum (b) as compared with spectrum (a). Spectrum (c) is from the same infant as (b) but without removal of the broad underlying hump which was due to relatively immobile ^{31}P in bone and membrane phospholipids. Peak identifications: (1) PME; (2) Pi; (3) PDE; (4) PCr; (5) γ -NTP; (6) α -NTP; (7) β -NTP. (Reproduced by permission of Plenum Press from E. B. Cady, 'Clinical Magnetic Resonance Spectroscopy', New York, 1990, p. 86)

[glycerolphosphorylethanolamine (GPE) and glycerolphosphorylcholine (GPC)]. The membrane bilayer phospholipids exhibit chemical shift anisotropy leading to a reduced signal-to-noise ratio at higher field strengths (e.g. 4.7–7 T). The very broad underlying signal, shown in Figure 1(c), is due to more rigidly bound ^{31}P nuclei mainly in membrane phospholipids and myelin.

Well resolved ^1H spectra can be acquired from the brains of newborn infants if long echo times (TE) are used (e.g. 270 ms). In Figure 2 an *in vivo* spectrum from a normal newborn infant is compared with an *in vitro* high-resolution spectrum of adult rat brain extract.²⁷ The major *in vivo* peaks originate from Cho, Cr, and NAA; a smaller but clearly detectable Lac methyl resonance is also present. In the extract spectrum, Cho is seen to include GPC, PC, and taurine, and NAA is adjacent to glutamate, glutamine, and γ -aminobutyric acid (GABA). At shorter TE times (e.g. about 25 ms), T_2 relaxation and phase modulation are less important and numerous peaks are easily detected; however, ^1H spectra become more difficult to analyze. This problem is further complicated by the presence of

many broad overlapping resonances from fatty acids (from extravoxel contamination and perhaps also free fatty acids) and macromolecules (e.g. proteins). Unlike ^{31}P metabolites, whose biochemical pathways are largely known, many ^1H resonances other than Lac still pose problems of interpretation.²⁸ For example, although NAA is widely regarded as an intraneuronal marker, its biochemical role remains unclear and NAA has also been found in oligodendrocyte progenitor cells.²⁹

4.2 Changes with Age

Age-dependent changes in the concentration ratios and absolute concentrations of ^{31}P and ^1H metabolites have been defined in several studies. A major reason for doing these investigations has been to establish normal age-related values so that metabolic abnormalities may be securely identified. Attention has focused on the rapid changes taking place in the last 3 months of gestation as determined in preterm and term infants studied during the first days of life. Investigations of development during later childhood have also been undertaken. Figure

Figure 2 An in vivo ¹H PRESS spectrum from the thalamic region of a normal newborn infant of GPA 35 weeks (a) compared with an in vitro spectrum of an extract of adult rat brain (b). Spectrum (a) was collected at 100 MHz and the acquisition conditions were: *TE* 270 ms; repetition time (*TR*) 2 s, 128 averaged echoes; and an 8 mL voxel. Resonance identifications: Cho, choline containing compounds; Cr, creatine + phosphocreatine; NAA, *N*-acetylaspartate; Lac, lactate. Spectrum (b) was obtained at 360 MHz with *TR* 3 s and a 90° flip angle (water-suppressed single pulse sequence). [Spectrum (a) was obtained in collaboration with A. Lorek, J. Penrice, J. S. Wyatt, R. Aldridge, and M. Wylezinska. Spectrum (b) is reproduced by permission of Elsevier Science Publishers from S. Cerdan, R. Parrilla, J. Santoro, and M. Rico, *FEBS Lett.*, 1985, **187**, 167]

Figure 3 Relations between ^{31}P metabolite concentration ratios in the temporo-parietal cortex and GPA in 30 infants of appropriate weight for gestational age. Regression lines and 95% confidence limits are shown. (Reproduced by permission of International Pediatric Research Foundation Inc. from D. Azzopardi, J. S. Wyatt, P. A. Hamilton, E. B. Cady, D. T. Delpy, P. L. Hope, and E. O. R. Reynolds, *Pediatr. Res.*, 1989, **25**, 440)

3 and Table 1 give ^{31}P surface coil data from the temporo-parietal cortex of 30 infants of appropriate weight for gestational age (AGA) studied at a median postnatal age of 4 days.³⁰ It can be seen that, with increasing gestational plus postnatal age (GPA), $[\text{PCr}]/[\text{Pi}]$ and $[\text{PDE}]/[\text{total mobile phosphorus } (P_{\text{tot}})]$ increased, whereas $[\text{PME}]/[P_{\text{tot}}]$ fell. These alterations, together with an increase in $[\text{PCr}]/[\text{NTP}]$, continue during the first months of life, but then the changes slow down as adulthood is approached (see Figures 4 and 5).¹³ Adult values are attained by about 4 years. Values from normal, small-for-gestational-age (SGA; i.e. with birthweights below the 3rd centile for gestation) infants were similar to those from AGA infants.³⁰ $[\text{PCr}]/[\text{Pi}]$ is directly related to the phosphoryl-

ation potential and to the free energy change of hydrolysis of ATP. The increase in $[\text{PCr}]/[\text{Pi}]$ with age may be attributable to a greater need for an energy reserve in the mature brain and perhaps also to less efficient oxidative phosphorylation in the immature one. In the newborn human infant, $[\text{PCr}]/[\text{Pi}]$ is similar to that in other altricial species, such as the newborn rat,³¹ but smaller than in precocious animals such as the lamb.³²

The large amplitude of the PME resonance in the neonatal period is due to high $[\text{PEt}]$.^{33,34} This metabolite may have an important role as a phospholipid precursor related to increased synthesis of membrane phospholipids and myelin at this time. Of the ^{31}P resonances only PME shows a change in relaxation with development; T_1 decreases from a neonatal value of about

Res.*, 1989, **25**, 440)

Figure 4 ^{31}P ISIS spectra from the paraventricular region of the human brain at postnatal ages of 1 month (a), 4 months (b), 30 months (c), and 15 years (d). The spectra were obtained at 1.5 T using a sensitive volume varying from 54 mL in infants to 72 mL in older children. TR was 3.75 s and 256 FIDs were averaged. Significant developmental changes occurred within the first few years of life. (Reproduced by permission of The Radiological Society of North America from M. S. Van der Knaap, J. van der Grond, P. C. van Rijen, J. A. J. Faber, J. Valk, and K. Willemse, *Radiology*, 1990, **176**, 509)

1.8 ms to about 1.2 ms in adulthood.¹⁸ This fall is probably due to alterations in the constituents of the peak, notably the reduction in P_{Et}. No change has been detected in pH_i during maturation (pH_i $\approx$ 7.10).^{13,30}

Measurements of the absolute concentrations of ^{31}P metabolites in the newborn human brain obtained by PRESS¹⁷ and ISIS¹⁸ techniques have shown disagreements. For example, with the ISIS technique, the apparent [NTP] was much less than estimated with the PRESS method. These discrepancies could be due to a number of factors, including the acquisition of data from different parts of the brain. Furthermore, ISIS and PRESS estimates of [PDE] may be affected by relaxation during the delays and the pulses of the acquisition sequence; the cross-linked membrane bilayer fraction of PDE has a T_2 of about 3 ms.³⁵

As with ^{31}P metabolites, the relative peak areas^{13,19,36} and absolute concentrations^{17,19} of ^1H metabolites change with increasing age (see Figures 6–8). NAA/Cr increases and Cho/Cr decreases up to about 3 years when the rate of change declines. [NAA] and [Cr] both appear to increase with age,

whereas both [Cho] and [myoinositol] decrease.^{17,19,37} The relatively low NAA signal seen in younger subjects and the increase with age are supported by biochemical studies, indicating that [NAA] increases greatly during mammalian brain development.³⁸ Since NAA is mainly located in neurons, this increase may reflect neuronal maturation. The Cho peak contains signals from PCh, GPC and other metabolites; changes in its amplitude probably relate to alterations in the PME and PDE peaks in ^{31}P spectra. Recent evidence suggests that Lac is detectable in the brains of normal newborn infants [see Figure 2(a)] and is higher in preterm and SGA infants. The implied greater reliance on anaerobic glycolysis in preterm and SGA infants may relate to their reduced values for [PCr]/[Pi].^{17,36}

5 CEREBRAL PATHOLOGY

^{31}P MRS has proved particularly valuable for the investigation of hypoxic-ischemic brain injury, especially in newborn infants. Most of the data have been acquired from infants who

Figure 5 Relationships between age and PME/β-NTP (a), PME/PCr (b), PDE/β-NTP (c), Pi/β-NTP (d), PCr/β-NTP (e), and PCr/Pi (f) in the paraventricular region. Regression lines and 2.5 and 97.5 percentile lines are shown. (Reproduced by permission of The Radiological Society of North America from M. S. Van der Knaap, J. van der Grond, P. C. van Rijen, J. A. J. Faber, J. Valk, and K. Willemse, *Radiology*, 1990, **176**, 509)

have suffered birth asphyxia, but similar results have been obtained in those with periventricular leukomalacia and other forms of hypoxic ischemic injury. More recently, ^1H MRS has been used for monitoring abnormal glycolytic pathway activity (via increased Lac) and neuronal degeneration (via decreased NAA).

5.1 Perinatal-Hypoxia Ischemia

Studies of babies with suspected cerebral hypoxic-ischemic injury were initiated on the premise that in conditions where the supply of oxygen to the brain was curtailed, or the mitochondrial mechanisms for its consumption were damaged, [ATP] would tend to fall. It was expected that the decrease in [ATP] would initially be very small because, unless [PCr] is grossly depleted, [ATP] is buffered by the creatine kinase reaction³⁹ which maintains it close to normal, but at the expense of a fall in [PCr] and a reciprocal rise in [Pi]. It was hypothesized that [PCr]/[Pi] in the brains of infants with hypoxic ischemic injury would be reduced and that, in extreme circumstances, [ATP] might also be low. Surprisingly, studies of severely birth-asphyxiated babies have shown that cerebral ^{31}P spectra

were often normal on the first day of life.⁴⁰ Subsequently [PCr]/[Pi] gradually fell, with a nadir at 2–4 days of age (see Figure 9 and Table 2), in spite of normal arterial oxygen saturation, blood pressure, and blood glucose. In the most affected infants, [NTP] then fell and death ensued. In contrast to the profound intracellular acidosis seen in experimental hypoxia-ischemia,³² pH_i tended to be slightly alkaline. (It is of interest that PCr and NTP were almost undetectable in two infants with inborn metabolic errors, propionic acidemia and arginosuccinic aciduria.⁴¹ However, cerebral pH_i was profoundly acidic in these infants.) In survivors, the spectra usually returned to normal within about 2 weeks, but the overall ^{31}P signal amplitude was often reduced, indicating loss of brain cells.

Since the lowest observed [PCr]/[Pi] values were strongly related to long-term prognosis (see below) and because of the long timescale of the postnatal biochemical changes, in order not to miss useful information it is important that spectra are obtained on several occasions during the first 2–4 days of life during which metabolic abnormalities are at their greatest. An explanation for the observed sequence of spectral changes is that the brain suffered an acute episode of hypoxia-ischemia before birth causing 'primary' energy failure, which was reversed by resuscitation at delivery, so that the energy state of

Figure 6 ^1H STEAM spectra obtained from (a) the parietooccipital cortex (predominantly white matter) and (b) the midline occipital cortex (mostly gray matter) of human brain at the ages of 4 days, 5 months, 4 years and from an adult. Amplitude scales have been adjusted so that absolute differences depending on both development and location can be visualized directly. Acquisition conditions: TR 2.87 s; mixing time (TM) 13 ms; TE 272 ms. Peak assignments: Ch, choline containing compounds; Cr, creatine + phosphocreatine; NAA, *N*-acetylaspartate; Glx, glutamate and glutamine; ML, myo-inositol; Lac, lactate; CH_2/CH_3 , lipid. (Reproduced by permission of Williams and Wilkins from R. Kreis, T. Ernst, and B. D. Ross, *Magn. Reson. Med.*, 1993, **30**, 424)

the brain returned to normal. The subsequent changes in ^{31}P spectra have been attributed to a 'secondary' impairment or failure of energy generation set off by the primary phase or events associated with it.⁴¹ Studies using near-infrared spectroscopy (NIRS) in infants developing secondary energy failure have shown that both cerebral blood flow and blood volume are increased; continuing inadequate oxygen or substrate supply is therefore not likely to be causal.

Many mechanisms have been suggested to account for the progression from primary to secondary energy failure, which is associated with delayed neuronal death. For example, one possibility is that excitatory neurotransmitters, particularly glutamate, which are released at the synapses in response to acute hypoxia ischemia may, by stimulating *N*-methyl-D-aspartate (NMDA) and other receptors, cause massive calcium entry to

cells and damage to the mitochondrial electron transport chain. Other possible mechanisms include those involving prostanooids, nitric oxide, free radicals, immune mechanisms, phagocytes, growth factors, and impaired protein synthesis. Because of the relation between secondary energy failure and long-term prognosis, much effort is being made to explore the mechanisms involved and how to interrupt them, with a view to the cerebroprotective treatment of asphyxiated infants. The same mechanisms are likely to be involved in stroke in adults.

Some evidence is emerging from animal studies of the feasibility of cerebroprotection. The development of secondary energy failure has been modeled in the newborn piglet, giving ^{31}P MRS results closely resembling those seen in birth-asphyxiated human infants.⁴² This model is suitable

Figure 7 Relations between gestational age (GA) and cerebral peak-amplitude ratios at the same anatomical locations as in Figure 6. Acquisition conditions and resonance identifications are as in Figure 6. Cho/Cr and MI have been fitted to a monoexponential function, whereas the NAA/Cr fit is biexponential. (Reproduced by permission of Williams and Wilkins from R. Kreis, T. Ernst, and B. D. Ross, *Magn. Reson. Med.*, 1993, **30**, 424)

for testing clinically feasible cerebroprotective strategies, with the amelioration of secondary energy failure, as measured by ^{31}P and ^1H MRS, providing an initial end-point. Recently, mild hypothermia, applied after a severe cerebral hypoxic-ischemic insult, was shown to be markedly cerebroprotective in this model,⁴³ whereas intravenous magnesium sulfate was ineffective.⁴⁴

^1H MRS studies of infants with hypoxic-ischemia brain injury^{36,45,46} show that increased Lac (due to failure of oxidative phosphorylation and consequent anaerobic glycolysis), and occasionally also reduced NAA (due to neuronal death), may be detected (see Figure 10). The Lac/NAA peak area ratio is often high and this index may prove a sensitive marker of

cerebral injury. Reduced [NAA] has also been seen in newborn infants with a variety of nonfocal pathologies,¹⁹ and in children with generalized demyelination.⁴⁷ Abnormal ^1H spectra have been found in older children with a variety of inborn errors of metabolism, including increased NAA in Canavan's disease (see Figure 11), and increased Lac in Leigh, Schilder, and Cockayne disease, and also in neuroaxonal dystrophy.⁴⁷

5.2 Prognosis

The prognostic significance of secondary energy failure has been investigated by Azzopardi et al.⁴⁰ They studied 61 infants recruited because of evidence or suspicion of hypoxic

Figure 8 Absolute concentrations (mmol/kg brain tissue) of the main cerebral metabolites detectable by *in vivo* ^1H MRS. Unfilled symbols are data from parietal white matter [location (a) in Figure 6]; filled symbols are data from occipital gray matter [location (b) in Figure 6]. ($\square$, $\blacksquare$) Data points from both normal infants and subjects with no primary cerebral pathology; ($\diamond$, $\blacklozenge$) data points from infants with essentially normal neurological status for whom the eventual diagnosis was considered immaterial to the cerebral metabolite profile. The solid lines are best fits to the data; biexponential for [NAA] and monoexponential for [Cr], [Cho], and [MI]. (The dotted curve in the [Cr] plot is triexponential and appears to fit the data better.) The vertical dashed lines indicate term at 40.5 weeks gestational age. The horizontal dashed lines show the mean adult values measured at location (a) in Figure 6. (Reproduced by permission of Williams and Wilkins from R. Kreis, T. Ernst, and B. D. Ross, *Magn. Reson. Med.*, 1993, **30**, 424)

ischemic brain injury, many of whom had sustained birth asphyxia. Clear evidence was found that the chances of survival and the severity of neurodevelopmental impairments at 1 year of age were directly related to the maximum detected extent of energy failure during the first days of life, quantified as the minimum observed value for [PCr]/[Pi] (see Table 2 and

Figure 12). Furthermore, if [NTP]/[P_{tot}] fell, death was almost inevitable.

As a continuation of the same study, Roth et al.⁴⁸ recruited a further group of birth-asphyxiated infants, so that data from a total of 52 such infants were available for analysis. These infants had been in very poor condition at birth; their mean arterial base excess in cord blood shortly after delivery was -20 mmol L^{-1} , 38 had fits, and 26 required mechanical ventilation. The relation between minimum recorded [PCr]/[Pi] in the first days of life and neurodevelopmental outcome is illustrated in Figure 13. These data extend those of Azzopardi et al. and confirm the bad prognosis of secondary energy failure. The sensitivity, specificity and positive predictive value for death or multiple disabling impairments of values of [PCr]/[Pi] more than 2 SD below normal were 72%, 92%, and 91%, respectively. Roth et al. also found a relationship between minimum observed [PCr]/[Pi] and head growth. Although the infants had normal head circumferences at birth, head growth was slowest, leading to microcephaly, in those whose values for [PCr]/[Pi] fell the most. Further follow-up indicated that the severities of adverse outcomes at age 4 years were also closely related to the extent of cerebral energy impairment in the first week of life.⁴⁹

The results of these studies may be summed up as showing that secondary energy failure leads both to neurodevelopmental disabilities and to microcephaly. The worse the energy failure, the worse the outcome is likely to be.

^{31}P spectra from the brains of infants with increased echo densities on ultrasound scans are also often abnormal, showing reduced values for [PCr]/[Pi] and sometimes [NTP]/[P_{tot}] (see Table 2).^{40,50} Such echo densities are usually due to hypoxic ischemic injury or to hemorrhage. ^{31}P spectroscopy can be useful for segregating infants whose echo densities carry a relatively good, from those implying a bad, prognosis.

Data are becoming available which indicate that abnormal ^1H spectra also imply a bad prognosis.^{36,45} Observation of raised Lac and of reduced NAA appear predictive of an unfavorable outcome. Further investigations, including long-term follow-up, are required before definitive statements can be made.

6 CONCLUSIONS

The first *in vivo* MRS studies of the human brain were in newborn infants. Since these studies were carried out, investigations of older children and adults have been undertaken and developmental changes have been defined for ^{31}P and ^1H metabolites. For example, [PCr]/[Pi] rises with age, indicating increased phosphorylation potential, and [PME]/[PDE] falls. ^{31}P MRS has proved particularly useful for investigating the cerebral metabolic consequences of severe birth-asphyxia. Spectra are often normal shortly after birth, but then [PCr]/[Pi] and, in severe cases, [NTP]/[P_{tot}] gradually falls, reaching minimum values at 2–4 days of age. The extent of the falls in [PCr]/[Pi] and [NTP]/[P_{tot}] are strongly related to the likelihood of long-term neurodevelopmental impairments or death. These changes in ^{31}P metabolite concentrations have been termed 'secondary' cerebral energy failure, on the hypothesis that they were initiated by an episode of 'primary' energy failure taking

Figure 9 ^{31}P spectra from the temporo-parietal cortex of a birth-asphyxiated infant born at 37 weeks gestation. The postnatal ages at the times of study are given. Peak assignments are as in Figure 1. At age 8 h, $[\text{PCr}]/[\text{Pi}]$ was 0.99, $[\text{NTP}]/[\text{P}_{\text{tot}}]$ was 0.09 and pH_i was 7.06; pH_i increased to a maximum of 7.28 at 36 h. The minimum $[\text{PCr}]/[\text{Pi}]$ was 0.32 at 55 h, when $[\text{NTP}]/[\text{P}_{\text{tot}}]$ was 0.04 and pH_i was 6.99. The infant died aged 60 h. R. Reynolds, *Pediatr. Res.*, 1989, **25**, 445)

Table 2 Age-dependent Standard Deviation Scores (SDS) for Phosphorus Metabolite Concentration Ratios and pH_i in the temporo-parietal cortex of Newborn Infants Suspected of Hypoxic-ischemic Brain Injury^a

	All infants (<i>n</i> = 61)	Birth asphyxia (<i>n</i> = 40)	Postnatal asphyxia (<i>n</i> = 5)	Increased cerebral echodensities (<i>n</i> = 16)
PCr/Pi	-2.14 ± 2.10^b	-2.14 ± 2.19^b	-0.03 ± 0.76	-2.04 ± 1.78^b
NTP/P _{tot}	-0.98 ± 1.86^c	-1.17 ± 1.82^c	-0.01 ± 1.03	-0.83 ± 1.99
PCr/P _{tot}	-1.72 ± 2.58^b	-1.79 ± 2.59^b	0.33 ± 1.04	-2.19 ± 2.52^b
Pi/P _{tot}	5.40 ± 8.77^b	5.97 ± 8.91^b	0.69 ± 0.99	5.51 ± 9.06^c
PME/P _{tot}	0.42 ± 1.69	0.63 ± 1.58	-0.79 ± 1.26	0.30 ± 1.83
PDE/P _{tot}	0.44 ± 1.43	-0.60 ± 1.44^d	0.39 ± 0.50	-0.32 ± 1.47
PCr/NTP	0.52 ± 2.98	0.65 ± 3.14	0.15 ± 0.66	0.31 ± 2.91
Pi/NTP	7.21 ± 16.41^b	8.96 ± 17.94^b	0.35 ± 1.06	4.94 ± 13.27^c
PME/NTP	1.94 ± 4.40^d	2.49 ± 4.71^c	-0.26 ± 1.11	1.25 ± 3.72
PDE/NTP	1.02 ± 3.84	1.43 ± 4.48	0.17 ± 0.77	0.23 ± 1.81
pH_i	0.05 ± 1.47 (<i>n</i> = 55)	0.23 ± 0.97 (<i>n</i> = 36)	-0.28 ± 0.22 (<i>n</i> = 5)	0.00 ± 2.21 (<i>n</i> = 14)

^aValues are those obtained when PCr/Pi was at its lowest. Mean values for SDS $\pm$ SD vs the normal control infants (see Table 1) are given.

^b $p < 0.001$. ^c $p < 0.01$. ^d $p < 0.05$. (Reproduced by permission of International Pediatric Research Foundation Inc. from D. Azzopardi, J. S. Wyatt, E. B. Cady, D. T. Delpy, J. Baudin, A. L. Stewart, P. L. Hope, P. A. Hamilton, and E. O. R. Reynolds, *Pediatr. Res.*, 1989, **25**, 445)

Figure 10 ^1H PRESS spectra acquired at 100 MHz from the thalamus of a severely birth-asphyxiated term infant. The ages at which the spectra were acquired are shown. Acquisition conditions: TE 270 ms; TR 2 s; 128 averaged echoes; 8 mL voxel. The lactate peak at about 1.3 ppm is greatly increased when compared with normal infants [see Figure 2(a)], although this may be partly due to raised free fatty acids. The peak at about 1.1 ppm is due to propan-1,2-diol (PD; the injection medium for phenobarbitone and phenytoin preparations). (Reproduced by permission of Williams and Wilkins from E. B. Cady, A. Lorek, J. Penrice, E. O. R. Reynolds, R. A. Iles, S. P. Burns, G. A. Coutts, and F. M. Cowan, *Magn. Reson. Med.*, 1994, **32**, 764)

place shortly before or during delivery. The prognostic information acquired by ^{31}P MRS is valuable for guiding the clinical care of infants suspected of hypoxic ischemic brain injury. In the future, the prevention of secondary energy failure, as measured by MRS, may be used to test the efficacy of cerebro-protective strategies. ^1H spectroscopy has demonstrated increased Lac/NAA peak area ratios in the brains of asphyxiated infants and this may also have prognostic significance.

Recent technological developments will enhance the value of MRS to clinical pediatrics. Five major areas have potential for immediate improvement: the development of special neonatal head probes to increase the signal-to-noise ratio; optimized acquisition methods to enhance the quality and variety of spectroscopic information; spectroscopic quantification; and spectral editing to detect resonances that would otherwise be difficult to resolve. Spectroscopic imaging for metabolite

Figure 11 ^1H PRESS spectra from occipital voxels in the brain of a 7-month-old child with Canavan disease (a) and in that of an age-matched, normal control (b). Spectrum (a) shows increased *N*-acetylaspartate (NAA) signal, and the resonance from choline-containing compounds (Cho) is almost undetectable. Canavan disease has been linked with high body fluid levels of NAA caused by aspartoacylase deficiency. The disease also affects myelin sheaths due to a defect of myelin formation and/or glial metabolism, and this may be the reason for the low Cho signal. Research interests: noninvasive investigation of perinatal brain injury, in particular employing ultrasound imaging, NMR spectroscopy, and near-infrared spectroscopy.

Central Nervous System Degenerative Disease Observed by MRI

Frank J. Lexa

Leonard Davis Institute of Health Economics, University of Pennsylvania, Philadelphia, PA, USA

1 INTRODUCTION

The degenerative diseases encompass some of the most interesting and important pathological entities in clinical medicine. In the past decade, MR imaging (MRI) has emerged as the premier radiological method for examining the brain and spinal cord. MRI has many advantages over computerized tomography (CT) for the detection of subtle changes in white and gray matter structures. This has led to the ability finally to detect and characterize some of these diseases early in their course without resorting to invasive techniques. This section will discuss the use of MRI to detect and characterize neural degeneration, beginning with the general case of the processes of Wallerian degeneration, which are common to many types of brain injury, and then move on to discuss the salient clinical and imaging features of the most important and best characterized of the neurodegenerative disorders. In the interest of brevity, only the most important clinical and imaging facets of the diseases will be covered. The reader is referred to two standard texts which are able to provide a more comprehensive discussion and bibliography.^{1,2}

2 WALLERIAN DEGENERATION: THE NEURONAL REACTION TO INJURY

Waller is credited for making the first histological description of the series of events which occur in the distal axonal segment following a proximal injury.³⁻⁵ This can occur after a wide variety of insults to the brain or spinal cord and thus represents an important marker of significant central nervous system (CNS) damage. The earliest phase is cessation of axonal transport, and collapse of the axonal segment.⁶ The myelin begins to fragment, and the Schmidt-Lanterman incisures open up. This is followed by reaction of the surrounding tissue with cellular proliferation and edema, during which the myelin is chemically degraded and removed. This eventually leads to formation of a gliotic scar.

Until the advent of MRI, it was difficult or impossible to detect degeneration of axonal pathways using antemortem imaging techniques. CT is usually only capable of detecting significant volume loss in end-stage cases. Early reports of the MRI appearance of Wallerian degeneration described T_1 and T_2 prolongation along corticofugal pathways in patients with acquired lesions such as strokes and Schilder's disease.⁷⁻¹³ In these reports, the lesions were at least several months old when

they had these signal characteristics, although these changes have been reported to be observable earlier.¹⁴ Observations from the first month were reported in which no abnormality could be detected.¹⁵ High signal intensity in the dentatorubral-thalamic tract has been reported after dentate nucleus resection.¹⁶

Other reports described a more complex pattern with no detectable signal changes in approximately the first month, a transient period of hypointensity on long TR images at approximately 1 month, followed by normalization of that hypointensity and later development of the more familiar T_1 and T_2 prolongation effects at approximately the 3-4 month mark.¹⁷⁻¹⁸ Recent work suggests that fast spin echo (FSE) imaging shows this early hypointense phase of Wallerian degeneration more conspicuously than conventional proton density imaging.¹⁹ In clinical medicine, this has important implications for the diagnosis and treatment of brain injury.

Animal models have been used to address the controversies raised by the above studies. Magnetic resonance spectroscopy of peripheral nerves showed significant increases in T_1 and T_2 relaxation times 15 days after sectioning the sciatic nerve.²⁰ Imaging of the tibial nerve confirmed that the T_2 signal intensity was elevated on long TR/TE images at day 15 in a crush injury model.²¹ Histological confirmation of Wallerian degeneration was obtained in a feline model of radiation injury. These areas showed high signal intensity on long TR/TE images over 200 days after radiation injury.²²

Newer techniques utilizing magnetization transfer techniques appear very promising for the early detection and separation of some of these changes. Using a cortical ablation model, Lexa et al. were able to demonstrate changes as early as the first week after injury (Figure 1).²³ Magnetization transfer images detected degenerating tracts at a distance from the primary injury site before conventional spin echo images or even routine light microscopy showed significant evidence of injury. Electron microscopy confirmed that the first phase of Wallerian degeneration was underway (Figure 2). Myelin degeneration and cellular degeneration were not detectable by light-microscopic techniques until significantly later. Moreover, the biphasic nature of the early changes in magnetization transfer suggests that it may be possible to separate some of the processes occurring in early axonal injury with magnetization transfer (Figure 3).

3 DEGENERATIVE DEMENTING ILLNESSES: ALZHEIMER'S AND PICK'S DISEASES

Alzheimer's disease is both the commonest cause of dementing illness as well as one of the most common causes of death in the industrialized countries. Both pathological and radiological studies demonstrate extensive atrophy, particularly of the hippocampus.^{24,25}

Pick's disease is a much rarer dementing illness with similar cognitive deficits to Alzheimer's disease; however, abnormal behaviors, apathy, abulia, and the Klüver-Bucy syndrome are more common.²⁶ The disease appears to be transmitted in a dominant, although modified, fashion, and is more common in females.

Neuroradiological studies and gross pathology show findings of marked atrophy affecting the frontal and anterior

Figure 1 Demonstration of changes in magnetization transfer in a feline model of Wallerian degeneration at 1.5 T. The x axis shows the number of days postplacement of a cortical lesion. The y axis shows the change in the magnetization transfer ratio (MTR) of the affected side relative to a control in three structures: the degenerating superolateral white matter ($\triangle$), remote white matter ($\blacklozenge$), and the ipsilateral lateral geniculate nucleus (+). The ipsilateral white matter tracts show an early rise and later fall in magnetization transfer as early degeneration progresses. (Reproduced by permission of The American Society of Neuroradiology from Lexa et al.²³)

temporal lobes with relative sparing of the parietal lobes and sparing of the posterior portion of the superior temporal gyrus and the occipital regions.²⁶ Alzheimer's disease appears to have associations with other degenerative diseases of the CNS—

Figure 2 Electron micrograph of white matter immediately superior to the lateral geniculate nucleus 8 days after ablation of the cortical sites of visual processing. Arrows mark examples of early degeneration with axonal collapse and increased cytoplasmic staining. (Reproduced by permission of The American Society of Neuroradiology from Lexa et al.²³)

Figure 3 Long TR FSE images in a woman 4 weeks after a middle cerebral artery stroke showing evidence of Wallerian degeneration in the ipsilateral corticospinal tract with marked signal loss (arrow) relative to the unaffected side

most notably Parkinson's disease (see below). In some reports, close to half of those patients with Alzheimer's disease have evidence of the degenerative changes associated with Parkinson's disease.^{27,28}

4 NORMAL PRESSURE HYDROCEPHALUS

Hydrocephalus can occur secondary to a wide variety of etiologies. This discussion will be limited to the 'degenerative' form of normal pressure hydrocephalus (NPH).

The syndrome of NPH is seen predominately in older patients, and includes a triad of clinical findings—dementia, gait ataxia, and urinary incontinence. The underlying mechanism which leads to NPH is controversial and includes theories related to diminished absorption from prior hemorrhage or inflammatory disease, changes in the physical properties of the ventricular walls, or, rarely, a preexisting congenital form of hydrocephalus. Patients may respond to shunting, and favorable factors include response to a preliminary trial of cerebrospinal fluid removal, presentation with gait disturbance, and short duration of symptoms.²⁹ NPH and white matter ischemic disease appear to be significantly related, including a direct correlation of the severity of the diseases.³⁰

On cross-sectional imaging techniques, NPH may overlap significantly in appearance with other diseases in this age group. In particular, the overlap with atrophy from other causes is problematic. The most useful features are those found in

other forms of hydrocephalus: thinning and elevation of the corpus callosum, and distention of the third ventricle.³¹

MRI may provide an additional clue by allowing detection and quantification of flow in the cerebral aqueduct. The magnitude of flow in this structure is increased in the setting of NPH, and is probably secondary to the diminished compliance of the ventricular system.³²

5 DEGENERATION OF THE CENTRAL GRAY MATTER STRUCTURES

5.1 Huntington's Chorea

Huntington's chorea is an autosomal dominant degenerative disease which has been localized to chromosome 4.³³ Presentation is in the fourth and fifth decades, with choreoathetosis and dementia. Neuroradiological studies confirm characteristic atrophy of the caudate and putamen as well as more generalized atrophy.³⁴ On MRI, abnormal signal intensity on long *TR*/*TE* images may be present in the striatum.

In addition to reductions in the caudate and putamen, detailed volumetric studies show volume loss in the thalamus and mesial temporal lobes.³⁵ In mildly affected individuals, the putaminal measurement appears to be sensitive and specific.³⁶

5.2 Wilson's Disease (Hepatolenticular Degeneration)

Wilson's disease is a genetic deficiency of ceruloplasmin, which leads to toxic copper deposition particularly in the liver and the lenticular nuclei of the brain. It is an autosomal recessive disorder which localizes to chromosome 13.³⁷ Clinical manifestations include liver disease, movement disorders of tremor, ataxia, dysarthria and rigidity, and psychiatric symptoms. The Kayser-Fleischer ring of copper deposition in Descemet's membrane is characteristic, while the definitive diagnosis is made by low serum ceruloplasmin, increased urinary copper, and elevated liver copper levels.

Atrophy, particularly of the gray matter, is a hallmark of Wilson's disease. Focal white matter lesions may occur which are hypointense on short *TR*, but of variable intensity on long *TR*.³⁸ These lesions appear to have a reversible component during appropriate therapy.^{38–40} Clinical neurological symptoms appear to correlate with the presence of radiological abnormalities. The location of lesions can be useful in predicting the type of neurological manifestation.⁴¹

5.3 Parkinson's Disease

Parkinson's syndrome, or Parkinsonism, is a broad clinical term referring to a cluster of symptoms due to loss of the majority of the dopaminergic efferent projections of the substantia nigra. The predominant clinical symptom is an involuntary tremor with rigidity and akinesia. The syndrome can be caused by a wide variety of etiologies, including stroke, trauma, inflammatory processes (particularly an epidemic which occurred after World War I, von Economo's encephalitis, now rarely with viral illnesses such as Cocksackie B, Japanese B and St. Louis viral encephalitides), drug effects, and associations with other degenerative diseases such as progressive supranuclear palsy, striatonigral degeneration, and Parkinson's disease. The

final common pathway is loss of the dopaminergic effects of these nigral projections on the striatal structures.

Parkinson's disease is a true degenerative disease of the CNS with idiopathic loss of nigral-striatal projections. This entity is common, with an age of onset in the 50–60 years range, affecting approximately 1 in 1000 of people over the age of 50 years.²⁷ The disease is progressive, probably due in part to ongoing loss of nigrostriatal function. Early in the course of the disease, patients may respond well to a variety of medications, often with progressive resistance as the degeneration advances.

On pathological examination, there are characteristic cell inclusions called Lewy bodies in the neurons of the substantia nigra, as well as in several related regions of the brain. MRI of Parkinson's disease patients reveals a decrement in the width of the pars compacta of the substantia nigra. This finding is shared with diseases leading to Parkinsonism such as striatonigral degeneration and progressive supranuclear palsy. Atrophy of the brain is also a characteristic that Parkinson's disease shares with other degenerative disorders, although sometimes this can be of a relatively small magnitude.

5.4 Striatonigral Degeneration

This degenerative disease presents with similar symptoms to Parkinson's disease. The primary differences rest with the much greater early involvement of the striatum (the putamen more than the caudate), which may in part explain the poor response to traditional Parkinsonism pharmacotherapy. This putaminal involvement may be detected on MRI with greater than normal hypointensity of the putamen on *T*₂-weighted sequences. The magnitude of this finding has been reported to correlate with the severity of clinical involvement.⁴² A second area of detectable involvement occurs in the substantia nigra, with loss of width of the pars compacta.

5.5 Progressive Supranuclear Palsy

Named for the presence of supranuclear ophthalmoplegia of vertical gaze, this syndrome includes manifestations of pseudo-bulbar palsy, rigidity, extrapyramidal signs, and dementia, presenting in late middle age and in the elderly population. This degenerative disease localizes predominantly to the mid-brain. In particular, the superior colliculi are atrophic, constituting a relatively specific MRI sign of the disease. Neurofibrillary tangles can be detected in the periaqueductal gray matter of the mesencephalon with gliosis—similar to the findings in Alzheimer's disease.^{43,44} Changes in this region can be seen on MRI, with high signal intensity on relatively *T*₂-weighted sequences.⁴³ As in the other degenerative diseases related to Parkinson's disease, there is diminished size of the pars compacta.

6 DEGENERATION OF THE CEREBELLUM AND BRAIN STEM

There are several degenerative diseases which have a propensity to attack the structures of the posterior fossa (Figure 4).

Figure 4 Sagittal T_1 -weighted MRI scan demonstrating idiopathic vermian atrophy in a patient with marked cerebellar symptoms

6.1 Down's Syndrome

Down's syndrome is a very important cause of inherited mental retardation. Supranormal amounts of the genetic material on chromosome 21 usually from nondisjunction are the underlying cause. MRI measurements show a global reduction in both gray and white matter. Interestingly, Down's syndrome is a very important risk factor for the ultimate development of Alzheimer's disease, with close to 100% of Down's patients developing a pathology similar to Alzheimer's disease in later life. The gene for the production of the amyloid- β protein which has been linked to some of the pathology in Alzheimer's disease also maps to chromosome 21. Reports of older patients with Down's syndrome (up to 64 years old) show significant widening of the temporal horns on MRI—similar to what has been reported in patients affected by Alzheimer's disease.⁴⁵ Finally, NMR spectroscopic analysis has shown a rapid decline in *N*-acetylaspartate (NAA)/choline in older Down's patients, which correlates well with onset of clinical symptoms and precedes atrophic changes.⁴⁶

6.2 Fragile X and Rett's Syndrome

The fragile X syndrome is a rare genetic cause of mental retardation. The syndrome is characterized by autism, repetitive movements, and hyperactive, self-destructive behaviors. The most profound expression is in males, but female carriers also show mild clinical and neuroradiological features of the disease. MRI reports have shown atrophy of the cerebellar vermis with concomitant enlargement of the fourth ventricle.⁴⁷

In contrast, Rett's syndrome is a disease of girls which manifests also with autism and stereotyped movements with loss of language and motor skills. The brain appears to have a globally decreased volume, particularly in the frontal lobes. This probably

occurs from a combination of congenital hypoplasia and perhaps ongoing degeneration—particularly in the cerebellum. The cerebellar loss is controversial, and other groups have shown greater effects on loss of gray matter volume.

6.3 Autism

Autism has been reported to be associated with findings of focal loss of volume in the superior vermis lobules (declive, folium, and tuber), as well as more generalized volume loss in other parts of the brain.⁴⁸ This finding has been contested by others.⁴⁹

6.4 Olivopontocerebellar Degeneration

This rare neurodegenerative disorder can be inherited or sporadic. Ataxia is the presenting sign, and can occur at any age. Because of the nonspecific nature of the presentation, MRI may be particularly useful in providing a specific diagnosis. Pathological and imaging findings include marked loss of volume in the body of the pons, middle cerebellar peduncles, cerebellum, and inferior olive. The pathways which interconnect these structures may show abnormal increased signal intensity on long *TR* sequences.⁵⁰ This probably depends on the stage of axonal degeneration.

6.5 Cerebellar Cortical Degeneration

Cerebellar cortical degeneration can present either with an early onset familial form or a late-onset sporadic form. There is a slowly progressive ataxia affecting the limbs, the trunk, and speech. Pathological examination and imaging studies both show marked cerebellar atrophy, particularly in the anterior vermis.

6.6 Acetazolamide-Responsive Familial Paroxysmal Ataxia

This unusual disorder is characterized by recurrent attacks of cerebellar symptoms which are associated with anterior vermian atrophy in the cerebellum.

6.7 Friedreich's Ataxia

Presenting in the second decade of life, this genetic degenerative disorder (localizing to chromosome 9 with multiple inheritance patterns) leads to a progressive ataxia. This leads to gait ataxia and difficulty with speech, as well as kyphoscoliosis, probably on a muscular basis. In addition, to the degeneration of the spinocerebellar tracts, there is loss of the posterior columns of the spinal cord. The spinal cord is atrophic, particularly in the posterior and lateral columns. The majority of subjects also have cerebellar atrophy; however, this is less pronounced than other processes which affect the cerebellum.

7 CONCLUSIONS

MR imaging has revolutionized the detection and diagnosis of many of the neurodegenerative diseases. The patterns of

atrophy and Wallerian degeneration in these entities often allow a specific diagnosis to be made noninvasively. Moreover, in the near future, advances in MRI such as magnetization transfer techniques may allow much earlier detection and characterization of the degenerative processes within the neuron which lead to these tragic diseases.

1 INTRODUCTION

The reader of this article will gain an understanding of the normal pathways of the cranial nerves and be able to correlate the function with the course of each nerve. The functional anatomy will also be addressed in conjunction with the clinical manifestations of pathologic entities. Tumors, infections, and inflammations of the cranial nerves will be discussed separately.

2 NORMAL ANATOMY

2.1 Cranial Nerve I (Olfactory)

Smell is consciously perceived in the gray matter covering the medial and lateral striae of the olfactory gyri. The lateral striae travel from the inferior medial aspect of the temporal lobe (pyriform area) and the medial striae from the medial and inferior aspects of the frontal lobe (subcallosal region) to the olfactory trigone located at the anterior perforated substance. The intermediate stria is not significant in humans, but joins the lateral and medial striae at the trigone to extend anteriorly as the olfactory tract. The olfactory tract terminates in the olfactory bulb. The olfactory bulbs are located inferior to the olfactory sulci (Figure 1). The olfactory sulci separate the gyri rectus from the medial orbitofrontal gyri.

Sensory nerve bundles exit the olfactory bulbs via the cribriform plate of the skull to separate into multiple neurosensory cells which reside in the nasal epithelium. The function of the olfactory nerve is to provide olfaction. Neuropathy of the first cranial nerve manifests as anosmia, or acute loss of olfaction. Anosmia is usually unilateral, and typically occurs secondary to pathologic processes arising in the nasal cavities. Intracranial neoplasms, infections, arterial disease, or congenital anomalies also can cause anosmia.¹

2.2 Cranial Nerve II (Optic)

The optic fibers originate in the calcarine portion of the occipital cortex and travel superiorly, inferiorly, and laterally to the occipital horn of the ventricle. The optic fibers then become the optic radiations as they course over the temporal horn of the lateral ventricle and the tail of the caudate nucleus to enter

the lateral geniculate body of the thalamus [Figure 2(a)]. Bilateral optic tracts then exit the lateral geniculate bodies and meet in the midline to form the optic chiasm. From the optic chiasm ventrally, the optic fibers then divide into the bilateral optic nerves coursing initially into the cranial openings of the optic canals. The optic nerves exit the orbital openings of the optic canals and extend forward in a sinusoidal manner to enter the globes at the optic nerve heads.

Lesions involving the intraorbital and prechiasmal portions of the optic nerve result in total monocular blindness. The sudden onset of a monocular deficit suggests a possible vascular or demyelinating process. The slow onset of a monocular optic neuropathy may be caused by a lesion intrinsic to the optic nerve sheath or secondary to extrinsic compression by an adjacent mass.

The fibers from the outer (temporal) portion of both visual fields cross at the optic chiasm and thus are carried via the optic tracts to the contralateral calcarine cortex of the occipital lobes. The fibers from the medial (nasal) portion of the visual fields do not cross at the optic chiasm and are projected to the ipsilateral visual cortex. Lesions involving the central portion of the chiasm particularly produce bitemporal hemianopsias. Lesions along the optic tracts result in loss of vision in the ipsilateral (uncrossed) nasal field and contralateral (crossed) temporal field. Since the retrochiasmal segment of the visual pathway recognizes the opposite visual field, a retrochiasmal lesion leads to a homonymous hemianopsia contralateral to the lesion. Contralateral hemianopsias may be produced by lesions involving any portion of the retrochiasmal optic pathways including the lateral geniculate bodies, the optic radiations, or the occipital cortices.¹⁻³

2.3 Cranial Nerve III (Oculomotor)

The motor component of cranial nerve III originates in the motor cortex of the cerebrum. The fibers then travel centrally

through the internal capsule to the ipsilateral superior colliculus. The fibers cross between the red nuclei in the dorsal tegmental decussation and continue distally in the paramedian raphe to synapse in the pontine reticular formation. The fibers then ascend in the medial longitudinal fasciculus to the oculomotor nucleus which is situated in the paramedian midbrain tegmentum ventral to the aqueduct of Sylvius at the level of the superior colliculus. At this level, additional fibers from the parasympathetic nucleus, paramedian nucleus, Perlia's nucleus, and Edinger–Westphal nucleus join the motor fibers. These combined fibers bow laterally to extend through the medial aspect of the red nucleus and the cerebral peduncle (Figure 2). Fibers then exit from the brainstem anteriorly at the pontomedullary junction near the midline where the two nerves form parallel structures in a V-configuration as they extend through the interpeduncular fossa (Figure 3).

The oculomotor nerves then travel between the superior cerebellar and posterior cerebral arteries through the prepontine cistern. Each cranial nerve III then penetrates the dura of the cavernous sinus and rises superiorly along the lateral wall of the cavernous sinus adjacent to the fourth cranial nerve and above the sixth cranial nerve and ophthalmic division of the fifth cranial nerve. The parasympathetic and motor fibers are in close proximity, and altogether the nerves penetrate the superior orbital fissure to reach the orbital structures.

The motor fibers provide the somatic motor function to the medial rectus, inferior rectus, superior rectus, and inferior oblique extraocular muscles. Lesions of this portion of the oculomotor nerve lead to a downward abducted eye, due to the unopposed action of the superior oblique and lateral rectus muscles. The oculomotor nerve also supplies the levator palpebrae superioris, which elevates the eyelid. Lesions of this portion of cranial nerve III also result in lid droop or ptosis. The visceral motor fibers from the Edinger–Westphal nucleus

provide parasympathetic motor function to the pupillary constrictor and ciliary muscles. Lesions of this portion of the oculomotor nerve result in pupillary dilatation due to unopposed sympathetic input and failure to accommodate. Isolated third-nerve palsies are regarded as either complete (including parasympathetic involvement) or incomplete (due to lack of parasympathetic involvement).¹⁻³

2.4 Cranial Nerve IV (Trochlear)

The motor impulses of cranial nerve IV originate in the motor cortex and then extend centrally via the internal capsule to the ipsilateral superior colliculus. The fibers cross between the red nuclei in the dorsal tegmental decussation and travel caudally in the paramedian raphe to synapse in the pontine reticular formation. The fibers then ascend in the medial longitudinal fasciculus to reach the motor nucleus. The fourth cranial nerve nucleus is located in the tegmentum of the mesencephalon at the level of the inferior colliculus immediately caudal to the third nerve nucleus. Fibers from the nucleus loop posteriorly to decussate in the tectum of the lower midbrain beneath the inferior colliculi. This pathway forms a sickle-shaped arch around the aqueduct of Sylvius (Figure 2).

The trochlear nerve exits from the dorsal aspect of the brainstem, emerging from the superior medullary vellum just beneath the inferior colliculus. The nerve extends around the cerebral peduncle between the superior cerebellar and posterior cerebral arteries, just lateral to the third cranial nerve (Figure 4). The nerve then pierces the dura of the cavernous sinus coursing along the superior margin adjacent to the oculomotor nerve and the ophthalmic portion of the trigeminal nerve en route to the superior orbital fissure.

Figure 4 Tectal and right trochlear nerve tumor in a patient with neurofibromatosis I. (a) Axial image at the level of the inferior colliculus. There is a hyperintense mass in the right tectum encompassing the nucleus of cranial nerve IV. Note the incidental dysplasia of the left sphenoid wing which is commonly seen in patients with NF-1. (b and c) Sagittal unenhanced images. There is a hypointense tumor expanding the inferior colliculus [arrow, (b)]. Note the expansion of the right trochlear nerve in the prepontine cistern [broad arrow, (c)]. (d) Axial enhanced image. The tumor foci in the tectal plate (white arrow) and in the right prepontine cistern (black arrow) do not enhance significantly. A hamartoma or low grade glioma is suspected. Note the uninvolved oculomotor nerves in the prepontine cistern

The fourth cranial nerve innervates the superior oblique muscle in the orbit. Lesions of the trochlear nerve or its nucleus result in outward rotation of the affected eye. Because the trochlear nerve has the longest intracranial course (7.5 cm), it has the greatest chance of injury from trauma or surgery in the region of the midbrain.^{1,3,4}

2.5 Cranial Nerve V (Sensory Trigeminal)

The sensory impulses from the upper, middle, and lower part of the face extend to the gasserian ganglion via the ophthalmic (V1), maxillary (V2), and mandibular (V3) branches of cranial nerve V. These branches enter the skull via

the superior orbital fissure, foramen rotundum and foramen ovale, respectively. The ophthalmic and maxillary divisions extend through the cavernous sinus, while the mandibular branch bypasses the cavernous sinus and directly enters the trigeminal (gasserian) ganglion. This ganglion lies in the inferior portion of Meckel's cavity and contains the cell bodies of numerous afferent sensory fibers. Facial numbness and burning (tic douloureux) represent signs and symptoms caused by sensory trigeminal neuropathies.

Sensory impulses from the face then leave the trigeminal ganglion to enter the midlateral pons through the prepontine cistern. As they enter the brainstem, branches go to the three sensory nuclei: the principal sensory nucleus, the mesencepha-

Figure 5 Plexiform neurofibroma involving the left trigeminal nerve. Adult patient with neurofibromatosis I. Enhanced images with fat saturation pulses. (a and b) Coronal images demonstrate the expansion and enhancement in the left maxillary division [arrow, (a)] and mandibular division [arrow, (b)] of the trigeminal nerve. (c and d) Axial images demonstrate the course of the left axillary nerve from the trigeminal ganglion through the foramen rotundum [arrows, (c)]. Note the expansion of the tumor into the left foramen ovale and pterygopalatine fossa [arrows, (d)]

lic nucleus, and the spinal nucleus. Pain and temperature fibers descend to the C2–C3 cord level where they synapse in the spinal nucleus of cranial nerve V. These fibers then cross the midline ascending in the ventral trigeminal lemniscus to reach the ventral posteromedial nucleus of the thalamus. The thalamocortical tract then carries the fibers via the internal capsule to the sensory cortex. The sensory impulses that mediate proprioception from the face, particularly of the mandible, synapse in the mesencephalic nucleus of cranial nerve V which extends superiorly into the periaqueductal gray matter of the midbrain. This portion of the sensory nucleus is composed of the sensory neurons that travel with the mandibular nerve. Sensory nerves that mediate touch and pressure from the face synapse in the principal sensory nucleus of cranial nerve V and travel to the ventral posteromedial nucleus of the thalamus via the contralateral dorsal trigeminal lemniscus. The extension to the sensory cortex is via the thalamocortical tract which passes through the internal capsule (Figure 2).^{1–3,5}

2.6 Cranial Nerve V (Motor Trigeminal)

The impulses for the motor components of cranial nerve V originate in the motor cortex of the cerebral hemisphere. The pathway then extends through the genu of the internal capsule and the cerebral peduncle (along the corticobulbar tract) to the motor nucleus which is situated medial to the principal sensory nucleus. The fused motor and sensory components of the fifth nerve emerge from the ventrolateral pons, coursing through the anterior portion of the cerebellopontine angle cistern near the apex of the medial petrous ridge. The nerve fibers then pierce the dura of Meckel's cavity and enter the trigeminal ganglion. At the distal aspect of Meckel's cavity, the motor fibers of the mandibular nerve exit at the inferolateral surface and extend through the foramen ovale (Figure 5). The motor division of the mandibular nerve supplies the muscles of mastication plus other small muscles (tensor villi palatini, mylohyoid, anterior belly of the digastric and tensor tympani).

Figure 6 Perineural extension of squamous cell carcinoma. Adult patient with previous known facial cancer. Coronal enhanced images. (a) Note the lateral deviation of the cavernous sinus wall and enhancement along the right trigeminal ganglion (arrow). (b) There is marked denervation atrophy of the right muscles of mastication. The fat which replaces the muscle shows moderate diffuse enhancement

The exit point of the motor trigeminal nerve from the brainstem is also the entry point of the sensory trigeminal nerve. This area is termed the 'root entry zone' of the sensory trigeminal nerve and is subject to vascular compression by dolichoectatic vessels or aneurysms which may cause tic douloureux or other trigeminal neuropathies. Alternatively, an ipsilateral or contralateral posterior fossa tumor or other mass lesion can torque the brainstem and cause a distention of this root entry zone. If the motor trigeminal portion is affected by a pathologic process, weakness of the muscles of mastication (with or without denervation atrophy) can occur (Figure 6).^{1-3,5}

2.7 Cranial Nerve VI (Abducens)

The impulses of cranial nerve VI originate in the motor cortex of the cerebral hemisphere. The fibers extend through the internal capsule and the corticobulbar tract to the ipsilateral superior colliculus. At this point, the fibers cross between the red nuclei in the dorsal tegmental decussation. They then extend caudally in the paramedian raphe of the brainstem to synapse in the pontine reticular formation. Both ipsilateral and contralateral fibers ascend in the medial longitudinal fasciculus to reach the brainstem nucleus of the abducens nerve which lies in the pons immediately anterior to the fourth ventricle. These fibers pass through the pontine tegmentum and exits anteriorly from the brainstem at the pontomedullary junction. The abducens nerve then courses superiorly and slightly laterally along the clivus. At the base of the dorsum sella, the sixth cranial nerve courses anteriorly piercing the dura through Dorello's canal to enter the cavernous sinus. The nerve then extends obliquely through the cavernous sinus just inferior and medial to cranial nerves III and IV, immediately adjacent to the cavernous portion of the internal carotid artery. Cranial nerve VI then exits anteriorly through the cavernous sinus to enter the superior oblique fissure en route to the lateral rectus muscle (Figure 2).

An isolated lateral rectus palsy is the most common lesion of the cranial nerves supplying the extraocular muscles. Injury to the abducens nerve produces paralysis of the ipsilateral lateral rectus muscle, with resultant horizontal diplopia. The unopposed pull of the medial rectus muscle causes the eye to turn inward (adduct), thereby producing internal strabismus.¹⁻³

2.8 Cranial Nerve VII (Facial)

The motor impulses of cranial nerve VII originate in the motor cortex of the cerebral hemisphere and extend via the genu of the internal capsule and cerebral peduncle to the brainstem nucleus. The motor nucleus of cranial nerve VII is situated in the caudal one-third of the ventral pontine tegmentum. Fibers from the ipsilateral and contralateral sides meet in this brainstem nucleus. From the nucleus, the fibers extend posteriorly toward the floor of the fourth ventricle and loop around the nucleus of cranial nerve VI (abducens). This portion of the facial nerve contributes to the facial colliculus, a mound of tissue that protrudes internally towards the floor of the fourth ventricle. Extending from the loop, cranial nerve VII emerges from the brainstem at the anterolateral aspect of the pontomedullary junction. The nerve then extends laterally in the cerebellopontine angle cistern reaching the anterior superior quadrant of the internal auditory canal. The facial nerve extends through the temporal bone to the fundus of the internal auditory canal. It then exits to join the geniculate ganglion within the roof of the petrous bone (Figure 7). At this point, there is a synapse with the sensory neurons for taste to the anterior two-thirds of the tongue and the cutaneous fibers for light touch in the region of the external ear.

The superior salivatory nucleus in the pons is the site of origin of the parasympathetic fibers that terminate in and stimulate the lacrimal, sublingual, and submandibular glands. The nucleus solitarius represents the end point of the fibers that convey taste sensation from the anterior two-thirds (via cranial

Figure 7 Axial enhanced images of the geniculate ganglion and proximal facial nerve schwannoma. (a) Note the tumor enhancement extending through the fundus of the left internal auditory canal to the geniculate ganglion (arrow). (b) The expansion of the tumor along the surface of the left petrous bone into the middle cranial fossa can be clearly seen (arrow)

nerve VII) and from the posterior third (via cranial nerve IX) of the tongue. The cell bodies of these taste fibers are found in the geniculate ganglion. The impulses from these nuclei form the intermediate nerve fibers which join the motor root of the facial nerve as it exits the brainstem (Figure 2).

From the region of the geniculate ganglion, the secretomotor fibers project forward as the greater superficial petrosal nerve which joins some parasympathetic fibers from the carotid artery to form the nerve of the pterygoid canal. The pterygoid canal will transmit the nerve to the pterygopalatine fossa from where the parasympathetic components synapse and fibers extend to affect lacrimation and salivation.

From the geniculate ganglion, the facial motor fibers and taste fibers form a 180° turn and are directed posteriorly, at the anterior genu of the facial nerve. Extending posteriorly, these fibers lie at the medial aspect of the tympanic cavity medial to the ossicular chain and below the lateral semicircular canal. At the posterior aspect of the middle ear, the motor and taste fibers extend inferiorly at the posterior genu of the facial nerve to enter the stylomastoid foramen. At this point, the stapedial nerve exits to supply the stapedial muscle which controls the mobility of the ossicles. The chorda tympani fibers for taste also separate from the seventh nerve within the stylomastoid foramen extending via the petrotympanic fissure and eventually joining the lingual branch of the mandibular nerve to participate in the sensory fibers for taste to the anterior two-thirds of the tongue. The seventh nerve then exits the stylomastoid foramen into the parotid gland and extends anteriorly to innervate the muscles of facial expression as well as the posterior belly of the digastric, the stylohyoid, and the platysma muscles.

Lesions of the facial nerve result in a facial palsy, which can be either peripheral or central. Central paralysis refers to a supranuclear injury that becomes manifest as paralysis of the contralateral muscles of facial expression, with sparing of the muscles of the forehead. Peripheral facial nerve function implies injury to the facial nerve from the level of the brainstem nucleus to the end of its motor fibers. All the ipsilateral muscles of facial expression are paralyzed in a peripheral injury. Dysfunction of the facial nerve branches within the greater superficial petrosal nerve is manifested as an impairment of ipsilateral lacrimation. Dysfunction of the stapedius branch of the facial nerve is manifested by hyperacusis. Dysfunction of the chorda tympani nerve causes loss of taste from the anterior two-thirds of the tongue. An impression on the 'root exit zone' of the facial nerve from the brainstem by a vascular anomaly may lead to spasmodic contractures of the ipsilateral muscles of facial expression (facial tic) (Figure 8).^{1-3,6}

2.9 Cranial Nerve VIII (Vestibular)

Movement impulses are modulated by the hair cells within the utricle, saccule, and three semicircular canals and transmitted through the superior and inferior vestibular nerves (Figure 9). The combined vestibular nerve courses along with the cochlear nerve and facial nerve within the internal auditory canal. The superior and inferior vestibular divisions enter the brainstem at the pontomedullary junction after crossing the cerebellopontine angle cistern. These fibers extend into the vestibular nuclear complex with postganglionic fibers carrying information regarding equilibrium to many coordination sites including the folliculonodular lobe of the cerebellum, the vestibulospinal tract, both medial longitudinal fasciculi and other pathways which affect the control of the eyes and the muscles of balance (Figure 2).¹⁻³

2.10 Cranial Nerve VIII (Cochlear)

Sound waves from the external environment are converted to energy in the inner ear in the form of vibratory impulses at the oval window of the vestibule. The kinetic impulses are propagated as fluid waves in the cochlea. These impulses are then converted to electrical impulses along the spiral organ of Corti. The auditory signals are then transmitted via the spiral ganglion in the cochlear nerve through the internal auditory canal and cerebellopontine angle to the origin of cranial nerve VIII at the ventrolateral pontomedullary junction. There are two cochlear nuclei (dorsal and ventral) located lateral to the inferior cerebellar peduncles in the upper medulla. The dorsal cochlear nucleus carries high frequencies, while the ventral cochlear nucleus connects low frequencies. Somewhat more than half of the fibers from these nuclei cross to the contralateral superior olivary nucleus to form the trapezoid body. From the trapezoid body, the fibers enter the posteriorly located lateral lemniscus to ascend to the inferior colliculus in the midbrain. From the inferior colliculus, the fibers travel to the medial geniculate body of the thalamus and then, via the auditory radiations to the superior temporal gyrus (Figure 2).

Clinical manifestations of acoustic pathway injury depend on the level of the injury. Lesions of the cochlear portion of the eighth nerve result in hearing loss and tinnitus (ringing or roaring in the ear). If unilateral sensorineural hearing loss is

Figure 8 Enhanced images of dolichoectasia of the basilar artery compressing the root exit zone of the left facial nerve. (a) This axial view shows an indentation by the basilar artery on the brainstem at the origin of the left facial nerve (open arrow). (b) This coronal view documents the tortuous course of the left basilar artery, including the brainstem compression at the origin of the facial nerve (arrow)

present, the injury has occurred somewhere between the cochlea and the cochlear nuclei of the brainstem. Unilateral involvement of the auditory pathway above the cochlear nuclei usually causes bilateral hearing loss due to the multiple crossings through the acoustic pathways. The hearing loss is greater in the ear contralateral to the site of the lesion. Cortical acoustic pathway lesions, which rarely cause disruption of auditory function, may result in auditory agnosia.^{1-3,7}

2.11 Cranial Nerve IX (Glossopharyngeal)

Impulses from the motor cortex of the cerebral hemisphere extend to the genu of the internal capsule and subsequently fol-

low the corticobulbar tract through the midbrain to the nucleus ambiguus. The fibers extend to the posterior olivary sulcus leaving the medulla at this point to extend anterolaterally to the superior and inferior glossopharyngeal ganglia situated in the jugular foramen. The fibers then travel inferiorly to supply the stylopharyngeus and constrictor muscles of the pharynx. In addition to this motor component to the muscles, there is a solitary nucleus for sensory fibers and a salivatory nucleus for parasympathetic fibers. These nuclei represent the primary sensory neurons for general visceral and special sensation, including taste, for the posterior third of the tongue (Figure 2).

The sensory portion of the glossopharyngeal nerve joins the motor portion which then extend together into the pars nervosa of the jugular foramen (Figure 10). There is a small tympanic branch (Jacobson's nerve) which supplies sensation to the middle ear and eustachian tube as well as parasympathetic fibers to the parotid gland. A small visceral branch supplies the carotid sinus and carotid body which controls the pressor and chemoreceptor functions. Pharyngeal sensory branches supply the posterior oropharynx and soft palate. The lingual branch includes fibers for both sensation and taste for the posterior third of the tongue.

Clinical manifestations of ninth nerve dysfunction include otalgia (referred pain along the tympanic branch to the ear), dysphagia (stylopharyngeus muscle dysfunction), and tachycardia or bradycardia with hypotension (sinus nerve dysfunction). Other symptoms definitely related to ninth nerve injury are loss of the afferent limb of the gag reflex and loss of taste to the posterior third of the tongue.¹⁻³

Figure 9 Vestibular schwannoma of the left utricle and saccule. (a) Unenhanced axial image. The small tumor of the membranous labyrinth is difficult to identify within the left petrous temporal bone (arrow). (b) Enhanced axial image. The bulbous tumor in the left vestibule is clearly shown (arrow)

Figure 10 Schwannoma of the right glossopharyngeal nerve in the jugular foramen. (a) Coronal image. The homogeneously hyperintense tumor smoothly expands the right jugular foramen. The apex of the tumor is along the brainstem with its inferior portion extending through the right side of the skull base. (b) Axial image. The homogeneously hyperintense tumor mass in the right side of the skull base is clearly seen on this T_2 -weighted image

2.12 Cranial Nerve X (Vagus)

Impulses from the motor cortex of the cerebral hemisphere travel through the genu of the internal capsule and cerebral peduncle via the corticobulbar tract to the nucleus ambiguus. The fibers extend to the posterior olivary sulcus slightly more lateral than cranial nerve IX exiting the medulla in the groove between the inferior peduncle and olive. Cranial nerve X continues an anterolateral course with its companion nerves (cranial nerve IX and the bulbar portion of cranial nerve XI) through the perimedullary cistern. The vagus nerve and bulbar portion of the eleventh cranial nerve enter the anterior aspect of the pars vascularis of the

jugular foramen. As previously discussed, the ninth cranial nerve enters the pars nervosa of the jugular foramen. After exiting the jugular foramen, the vagus nerve plunges like a plumb line along the posterolateral aspect of the carotid artery to the aortopulmonic window of the mediastinum on the left side and to the clavicle on the right side. The right recurrent laryngeal branch turns cephalad around the right subclavian artery, while the left recurrent laryngeal branch turns cephalad by looping through the aortopulmonic window. Both recurrent laryngeal nerves reach the larynx via the tracheoesophageal groove. Sensory fibers of the vagus nerve begin in the thoracoabdominal viscera and chemoreceptors at the aortic arch. These then synapse in the solitary nucleus (pure sensory fibers) and the dorsal motor nucleus (parasympathetic secretomotor fibers) (Figure 2).

Injury to the vagus nerve below the hyoid bone causes manifestations of recurrent laryngeal nerve malfunction and include hoarseness, aspiration, and cervical dysphagia. Injury to the vagus nerve above the hyoid bone results in the above symptoms in combination with oropharyngeal symptoms of uvular deviation and loss of the efferent limb of the gag reflex secondary to pharyngeal plexus malfunction. Proximal vagal neuropathy usually involves some combination of cranial nerves IX, X, XI, and XII.^{1-3,8}

2.13 Cranial Nerve XI (Spinal Accessory)

Impulses from the motor cortex of the cerebral hemisphere extend through the genu of the internal capsule and cerebral peduncle via the corticobulbar tract to the nucleus ambiguus. The motor fibers of the bulbar portion of the spinal accessory nerve are joined by additional fibers which arise from the anterior horn cells of the first five cervical cord segments. The fibers from the spinal nucleus have ascended through the foramen magnum. Together, the combined fibers from the bulbar and spinal portions of the spinal accessory nerve pass anteriorly to exit from the medulla at the posterior olivary sulcus. The eleventh cranial nerve joins the companion cranial nerves IX and X to pass through the perimesencephalic cistern. The spinal accessory nerve then leaves the skull via the posterior portion of the pars vascularis of the jugular foramen. From the skull base, the eleventh cranial nerve enters the carotid space and then quickly diverges posterolaterally to descend along the medial aspect of the sternocleidomastoid muscle. It then continues its course across the posterior triangle of the neck to terminate in the trapezius muscle.

Clinical manifestations of spinal accessory nerve injury are often found in conjunction with ninth, tenth, and twelfth nerve symptoms. When isolated, the symptoms will consist of shoulder droop and an inability to lift the arm.¹⁻³

2.14 Cranial Nerve XII (Hypoglossal)

Impulses from the motor cortex travel via the corona radiata through the genu of the internal capsule and cerebral peduncle via the corticobulbar tract to reach the hypoglossal nucleus, which is found in a paramedian location in the floor of the fourth ventricle. Hypoglossal nerve root fibers as well as fibers from the nucleus ambiguus exit forward from the medulla passing lateral to the medial lemniscus. The fibers exit from the

Figure 11 Multiple neurofibromas in a patient with neurofibromatosis I. There are bilateral neurofibromas in the carotid spaces which surround the carotid arteries. The lesions are readily identified by their high signal intensity (arrows). Additional smaller neurofibromas are seen in the posterior scalp region

brainstem in the sulcus between the pyramid and olive as multiple small rootlets. The rootlets extend anteriorly to form the hypoglossal nerve extending anterolaterally through the hypoglossal canal. Once exited from the skull base, the fibers descend inferiorly in the carotid space lying medial to cranial nerves IX, X, and XI and passing lateral to the carotid bifurcation. The hypoglossal nerve then continues forward to enter the posterior portion of the sublingual space of the oral cavity. From here it curves upward medially to the submandibular salivary glands to supply the intrinsic and extrinsic muscles of the tongue and the infrahyoid strap muscles.

Clinical manifestations of hypoglossal nerve injury include deviation of the tongue toward the side of the lesion on protrusion. Tongue atrophy, including both the intrinsic and extrinsic muscles will be evident in chronic lesions. Fasciculations of the tongue muscles may also be seen.¹⁻³

3 TUMORS OF CRANIAL NERVES

3.1 Neural Tumors

Schwannoma and neurofibroma are the two most common tumors of the cranial and peripheral nerves. Both tumors are derived from Schwann cells, but present quite differently. Schwannomas are usually solitary masses arising from more proximal nerves, while neurofibromas may be multiple, and usually arise in more distal nerves (Figure 11). Histologically, schwannomas show areas of high and low cellularity known as Antoni-A and Antoni-B areas, respectively, while neurofibromas show spindle cells with wavy nuclei not seen in schwannomas. Another differentiation between these two tumors is the presence of a capsule around schwannomas, whereas neurofibromas are usually not encapsulated. In many

cases, schwannomas can be removed by surgery without transecting the nerve. Neurofibromas, however, are part of the nerve which has to be excised with the tumor.

3.2 Schwannoma (Neurilemoma)

Schwannoma is a benign tumor which arises from the Schwann cells surrounding the cranial nerves, peripheral nerves and sympathetic plexus. The Schwann cells represent structures that both encircle the axons of the nerves and provide the nerves with mechanical support and their myelin sheaths. Histologically, a schwannoma contains a cellular component (formed from the Antoni-A cells) and a myxoid component (formed from the Antoni-B cells). The presence of these components and the absence of nerve fibers in the body of the tumor allow the pathologist to differentiate a schwannoma from a neurofibroma.

Schwannomas of the olfactory system and visual pathway are rare, since cranial nerves I and II are not true cranial nerves, but rather are embryologic invaginations of fiber tracts from the telencephalon and diencephalon. The remaining cranial nerves and the upper spinal nerves are the sites of origin of the majority of schwannomas. These tumors are more common in women aged 30–60 years. The signs and symptoms vary according to the specific site of origin.

Schwannomas of cranial nerves III, IV and VI may be seen along the cisternal, cavernous or intraorbital course of these nerves. Symptoms include diplopia, ophthalmoplegia or proptosis, depending upon the site of greatest mass effect. These tumors may be visualized on MRI as they course through the cranial canals. Bulbous expansion of the canals at the site of a lesion is considered pathognomonic; however, differentiation of schwannomas from various malignancies extending along nerve roots may be difficult.

Schwannomas of the trigeminal ganglion and trigeminal nerve usually cause progressive facial numbness, pain, and paresthesias. Some trigeminal tumors can attain a considerable size in the absence of facial pain or numbness, since they may arise from the nerve sheath and secondarily compress the nerve fibers. Schwannomas involving the trigeminal nerve are divided into three anatomical divisions: preganglionic, ganglionic, and postganglionic. Lesions that originate from the trigeminal ganglion typically straddle the incisura with a component extending into the cavernous sinus (postganglionic) and another portion extending into the prepontine cistern (preganglionic) (Figure 12).⁹⁻¹²

Facial nerve schwannomas may present with facial nerve palsy and/or hearing loss, or may be relatively asymptomatic. The development of facial nerve schwannomas from the nerve sheaths allows some of these tumors to enlarge and decompress into the adjacent air-containing cavities of the temporal bone without producing symptoms. Schwannomas originating from the geniculate ganglion typically become quite large without producing facial nerve dysfunction. These lesions may expand into the superior surface of the temporal bone and present as middle fossa masses (Figures 7 and 13).

Acoustic nerve schwannomas originate from the vestibulocochlear nerve along its course from the vestibule and cochlea, internal auditory canal, and cerebellopontine angle cistern. These tumors represent 5–10% of all primary intracranial neoplasms and approximately 85–90% of all cerebellopontine

Figure 12 Schwannoma of the right trigeminal ganglion. (a) There is a primarily hypointense lesion in the right Meckel's cave and trigeminal ganglion region (arrow). (b) This enhanced view documents homogeneous enhancement of the tumor mass (arrow)

angle tumors. The clinical symptoms of acoustic nerve schwannoma are typically unilateral or asymmetric neurosensory hearing loss. These symptoms are directly related to the size of the tumor. As the tumor enlarges and fills the internal auditory canal, it compresses the cochlear nerve, causing neurosensory hearing loss and tinnitus, which are the most common initial symptoms (Figure 13). The early hearing loss is of the high-frequency variety, which may be related to the anatomic arrangement of the high frequency fibers around the periphery of the nerve. The hearing loss is typically gradual and progressive, but may have an acute onset. Vestibular dysfunction, such as dizziness and disequilibrium, are relatively uncommon presenting symptoms, even though 85% of acoustic nerve schwannomas arise from the vestibular nerves. Small intracana-

licular lesions may be either relatively asymptomatic or may cause progressive symptoms. Some larger neoplasms may develop intramural or extramural hemorrhage with the sudden onset of headache, nausea, and vomiting. True central vertigo may be associated with brainstem involvement. Facial nerve dysfunction may be related to compression of the seventh nerve.

Jugular foramen schwannomas can originate from different sites along cranial nerves IX, X or XI. Early symptoms consist of loss of taste in the posterior third of the tongue (glossopharyngeal nerve), paralysis of the vocal cord and palate (vagus nerve), and paresis of the trapezius and sternocleidomastoid muscles (spinal accessory nerve). Proximal schwannomas may extend into the inferior portion of the posterior fossa, producing hearing loss, vertigo, ataxia, hoarseness, and swallowing difficulties (Figure 10). Schwannomas of the twelfth nerve usually cause hemiatrophy and paresis of the tongue. Some large tumors of the jugular foramen can extend into the hypoglossal canal and large hypoglossal schwannomas may expand into the adjacent jugular foramen. Concomitant involvement of cranial nerves IX, X, XI, and XII is rare, but may be seen with bulky tumors. Additional disturbances of posterior fossa function may include gait abnormalities, swallowing difficulties, dizziness, and vomiting. In the neck, schwannomas are the most common neoplasm of the carotid space and the second most common lesion of the parapharyngeal space. Clinical presentation is a painless, slow growing mass in the anterolateral neck or posterolateral oropharynx. These lesions may become painful with associated neuropathies if they continue to grow and compress the nerves.¹¹⁻¹³

The MRI appearance of all schwannomas is similar. The key differentiating point is the location of the central portion of the tumor within or near the nerve of origin. Schwannomas are fairly fusiform in appearance and well circumscribed because of their associated capsule. There may be smooth and uniform enlargement of the cranial canal through which the nerve is transmitted. The signal intensities, however, differ dramatically with respect to the size of the tumor. Smaller tumors usually appear homogeneous (since they are predominantly of the Antoni-A cell type), while larger tumors demonstrate heterogeneity and variable signal intensities owing to the presence of hemorrhage, necrosis, and cystic degeneration (Figure 13). Larger tumors typically contain many Antoni-B type cells. These schwannomas can have foci of high and low signal intensities on both the T_1 - and T_2 -weighted images. The presence of intramural cysts will characteristically produce foci of high signal intensity on the T_2 -weighted images (Figure 14).^{9,12}

One MRI study suggested that cystic changes in acoustic nerve schwannomas may be related to either intramural cysts (Figures 13 and 14) or extramural arachnoid cysts (Figure 15). The intramural cysts showed high signal intensity on the T_2 -weighted images, which was thought to be due to necrotic material, blood, or colloid-rich fluid. The extramural cysts showed high signal intensity related to higher protein and/or colloid contents secreted by the tumor. The extramural cysts were thought to originate from peritumoral adhesions which caused a pseudoduplication by the trapping effect of fluid between the leptomeninges and the schwannoma.¹⁴

Enhancement following gadolinium contrast administration is also variable, although it is typically rapid due to extravasation of contrast into the extracellular compartment of the often

Figure 13 Large schwannomas of the right seventh and eighth cranial nerves extending from the geniculate ganglion to the cerebellopontine angle (CPA). The patient had marked hearing loss, but only minimal facial nerve dysfunction. Enhanced images with fat saturation pulses. (a) This coronal image shows the tumor in the right CPA and internal auditory canal (arrow). (b and c) Axial images. The portion of the tumor in the right CPA shows both solid and cystic components (arrows). The solid component extends through the right internal auditory canal where it merges with a companion tumor in the right geniculate ganglion [arrow, (c)]

vascular schwannoma. In nearly all cases, there is a sharp demarcation between the margin of the tumor and the adjacent structures. Enhancement of the cranial nerves or their ganglia without an associated soft tissue mass is consistent with cranial nerve neuritis and/or ganglionitis rather than a neoplasm. Sarcomas, hemangiomas, or paragangliomas may have similar MRI enhancement characteristics and need to be considered in the differential diagnosis of schwannomas.^{12,15}

3.3 Neurofibroma

A neurofibroma contains neural elements with a fibrous core. This tumor may arise from the cranial, spinal, or peripheral nerves. The patient's symptoms depend upon the nerve of involvement and may be similar to the symptoms associated

with a schwannoma. In the extracranial head and neck, neurofibromas may present as subcutaneous soft tissue nodules in the skin or as a mass lesion in the carotid or parapharyngeal spaces (Figure 11). In such cases, the clinical symptoms result from tumor bulk and may include dysphagia or difficulty turning the neck. Some neurofibromas cause pain or other focal neurologic deficits.

Most neurofibromas are seen in young adult patients. Approximately 10% of patients with neurofibromas have neurofibromatosis type I (NF-1 or von Recklinghausen's disease). Two types of neurofibroma are known to be associated with NF-1. Multiple or single solid lesions may be seen along the cranial, spinal, or peripheral nerves (Figure 11). Another type of lesion presents as an infiltrating soft tissue mass with extension along the cranial nerves through the orbits, skull base, or

Figure 14 Acoustic nerve schwannoma with solid and intramural cystic components. (a) This axial image shows the heterogeneous mass in the left internal auditory canal and cerebellopontine angle cistern. The cystic component of the tumor merges with the bright signal intensity of the cerebrospinal fluid. (b) This axial enhanced image shows the solid and cystic components. Note that the cystic portion shows peripheral enhancement confirming an intramural cyst (arrow)

posterior fossa. This so-called 'plexiform' neurofibroma encases the muscles and soft tissues along the course of the nerves (Figure 5).¹⁶

The MRI characteristics of neurofibromas are quite varied and simulate schwannomas in many cases. Neurofibromas project an intermediate signal intensity on the T_1 - and proton-density-weighted images. They sometimes have a 'salt and pepper' appearance whenever there is intense vascularity within the stroma of the tumor. The T_2 -weighted images are variable, depending on whether the tumor is cystic or solid in nature. Variable enhancement is seen following gadolinium administration due to the presence of cystic areas, calcifications, or vascularity. The margins of a neurofibroma appear less distinct

than the margins of a schwannoma, because neurofibromas lack a capsule. In many cases, it may not be possible to differentiate a neurofibroma from a schwannoma on MRI characteristics.^{12,15}

3.4 Malignant Schwannoma

Many terms have been used to describe a malignant schwannoma, including malignant neurofibroma, neurofibrosarcoma, neurosarcoma, neurogenic sarcoma, malignant neurilemoma, and malignant nerve sheath tumor. Many malignant schwannomas contain interlacing fascicles of spindle cells in a herring-bone pattern, as typically seen in fibrosarcomas. Unlike fibrosarcomas, however, on electron microscopy malignant schwannomas are seen to contain basement membranes. The light microscopic findings include high cellularity, pleomorphism, high incidence of mitotic figures, presence of necrosis, and presence of histologic invasion. There is no capsule around a malignant fibrosarcoma.¹⁶

Malignant schwannomas are highly malignant lesions that recur following local excision in 50–80% of patients. The histologic grade is the most important factor in determining prognosis and is the primary factor considered in staging. Five-year survival rates in one study of 17 patients over the course of 37 years was 47%. Wide and aggressive excision with or without adjuvant radiation therapy is considered the best treatment alternative. Generally, patients with malignant schwannomas of the head and neck have a poorer prognosis than do those with similar tumors of the extremities, which can be treated with amputation. One factor contributing to the poor prognosis of this tumor is its resistance to radiation therapy.

The incidence of malignant schwannomas is approximately 5–10% of all sarcomas and 2–12% of all nerve sheath tumors. Patients with NF-1 have a 5–30% chance of developing a de novo malignant neurogenic tumor. The typical NF-1 patient with a malignant neural tumor is 20–50 years old. The 5-year survival rate in patients with NF-1 is 15–30%. Recurrences and metastases may occur as late as 5–10 years following treatment.

The tumor initially causes a fusiform, nodular swelling of the involved nerve and ultimately diffusely infiltrates the nerve. It then spreads into the surrounding soft tissues and often contains areas of hemorrhage or necrosis (Figure 16). The tumor may cause neurologic symptoms such as pain, paresthesias, atrophy, and muscle weakness. Occasionally, a symptomless mass along a nerve distribution is seen.^{12,15,16}

The MRI appearance is of a tubular mass along the involved nerve with regional extension into the skull base (cranial nerve) or cervical soft tissues. The signal intensity is varied, but is typically hypointense on the T_1 -weighted images and hyperintense on the T_2 -weighted images. Gadolinium contrast administration helps to outline the margins of the tumor including extension beyond the site of origin into the spinal canal or cranial cavity (Figure 17).^{12,15}

3.5 Cranial Nerve Seeding

Both metastatic neoplasms and primary malignant tumors of the central nervous system can disseminate via the subarachnoid cisternal pathways to distant locations. This type of

Figure 15 Acoustic nerve schwannoma with a small arachnoid cyst in the left cerebellopontine angle. (a and b) The large tumor is highly heterogeneous and deforms the left side of the brainstem and cerebellum. Note the homogeneously bright signal in the small left arachnoid cyst (arrows). (c) This image shows enhancement of the tumor. The arachnoid cyst, however, is extramural and does not enhance (arrows)

Figure 16 Malignant schwannoma of the right trigeminal and inferior alveolar nerves. Coronal enhanced images with fat saturation pulses. (a) This composite image documents the extensive infiltration of the tumor in the right muscles of mastication. There is a pathologic fracture of the right ramus of the mandible (arrows). (b) This composite view documents the extension of the tumor in a tubular manner through the right foramen ovale into the right trigeminal ganglion (arrows)

Figure 17 Coronal enhanced images of a malignant schwannoma of the right brachial plexus with intraspinal extension. (a and b) The tumor fills the region of the scalene muscles and brachial plexus. There is downward extrapleural extension [arrow, (a)]. Note a small intraspinal portion along the cervical nerve roots [arrow, (b)]

metastatic spread may be manifested as either a diffuse spread along the leptomeningeal surfaces of the brain or loculated deposits of tumor nodules along specific sites within the subarachnoid spaces such as the cranial nerves. The most common dissemination in children is from primitive neuroectodermal tumors and ependymomas. The most common cause of seeding in adults is from a glioblastoma multiforme. The incidence of seeding from a glioblastoma is less than 5% in all age groups. Other tumors that can seed to the leptomeninges or cranial nerves are sarcomas, carcinomas, and adenocarcinomas. Leptomeningeal metastases from various lymphoproliferative tumors are also common in both children and adults. Metastatic lymphomatous foci may be deposited adjacent to the cranial nerves along their courses through the posterior and middle cranial fossae (Figures 3 and 18).^{16,17}

Intracranial leptomeningeal metastases tend to be diffuse along the subarachnoid spaces and cranial nerves. Microscopically, the tumor cells infiltrate the leptomeninges as a single layer or as thicker, multilayered aggregates. The earliest infiltration is along cortical vessels and is limited to the perivascular Virchow–Robin spaces. Clinically, patients most often present with a variety of symptoms, which are usually multifocal. Headache, change of mental status, cranial nerve deficits, and gait disturbances are the most common.

These metastatic deposits are visualized best on the T_1 -weighted postcontrast images, particularly if fat saturation

Figure 18 Lymphomatous meningitis of the brainstem and cranial nerves. Axial enhanced images. There is a focal tumor nodule in the left cerebellopontine angle region [arrow, (a)]. There is diffuse infiltration of the midbrain and enhancement along the left trochlear nerve [arrow, (b)]

Figure 19 Axial enhanced image of seeding of metastatic adenocarcinoma to the subarachnoid spaces and cranial nerves. There are sheets and nodules of tumor surrounding the midpons and cerebellar folia. A large focal nodule occupies the origin and preganglionic portions of the left trigeminal nerve (arrow)

techniques are utilized. The areas of nodular or linear enhancement follow the contours of the meningeal surfaces or cranial nerves as they traverse through the cerebrospinal fluid (Figure 19). The T_2 -weighted images are less sensitive because of the surrounding high signal intensity of the cerebrospinal fluid.^{12,15}

3.6 Perineural Spread of Malignant Neoplasms

Perineural tumor extension is a form of metastatic disease in which primary tumors spread along neural pathways and gain access to noncontiguous regions. Since the treatment and prognosis are altered when perineural spread is identified, proper evaluation is critical. The infiltration of the nerves by tumor is best seen on gadolinium enhanced MRI.^{18,19}

Perineural tumor spread is visible as smooth thickening of the cranial or spinal nerves and/or concentric expansion of the foramina and fissures through which the nerves traverse. Involvement of the maxillary and mandibular divisions of the trigeminal nerve is common because of the large size of these branches and their strategic passage through the pterygopalatine fossa. In cases of perineural spread to the trigeminal ganglion, there may be replacement of the normal trigeminal cistern hypointensity by an isointense or enhancing soft tissue mass (Figure 20). Other signs of trigeminal ganglion involvement include lateral bulging of the cavernous sinus dural membranes and atrophy of the masticator muscles supplied by the trigeminal nerve branches (Figure 6). Perineural metastatic disease may occur along the course of the facial nerve, most commonly resulting from neoplasms of the parotid gland, particularly adenoid cystic carcinoma.^{15,18,19}

4 INFECTIONS AND INFLAMMATIONS OF CRANIAL NERVES

Infections of the cranial nerves commonly are caused by a latent virus such as herpes simplex I or varicella zoster. These neurotropic viruses tend to affect the cell bodies of the sensory neurons, in which they may reside for many years. Reactivation of the dormant virus results in a swelling of the involved ganglion or of the involved nerve. After contrast medium administration, there may be enhancement in the ganglion or along the course of an infected nerve.^{15,20}

The most common viral mononeuritis is Bell's palsy, which is thought to be caused by reactivation of a herpes simplex virus in the geniculate ganglion. Following gadolinium administration, there may be enhancement along the entire course of the facial nerve from the internal auditory canal through the mastoid foramen. More commonly, the portion of the facial nerve in the region adjacent to the geniculate ganglion is enhanced as a result of entrapment of the seventh cranial nerve in the fallopian canal (Figure 21). Herpes simplex trigeminal neuritis and ganglionitis have been described, revealing involvement of the fifth cranial nerve on contrast enhanced MRI (Figure 22).^{21,22}

The clinical prevalence of herpetic involvement of the cranial nerves is most likely underestimated. However, in patients infected with the human immunodeficiency virus (HIV), it is fairly common to recognize postgadolinium enhancement along one, two or more cranial nerves. The mechanism is similar to that of herpes simplex virus, since the HIV virus is also neurotropic and directly invades sensory ganglia and their associated nerves.^{20,21}

5 OPTIC NERVE AND SHEATH DISORDERS

Primary disorders of the optic nerve and optic nerve sheath typically cause visual disturbances and occasionally proptosis in cases of large neoplasms. The most common primary neoplasms of the optic nerve include gliomas (astrocytomas and hamartomas) or meningiomas. There may be a paraoptic component of optic nerve tumors, which is characteristically seen in patients with neurofibromatosis type I. The paraoptic component results from perineural arachnoidal gliomatosis, consisting of proteinaceous material that seeds and spreads within the optic nerve subarachnoid space and is a portion of the tumor. This process may result in optic nerve elongation and resultant kinking of the nerve just posterior to the posterior portion of the globe. There is no correlation between the size of the lesion and visual loss.

Extension of tumors into the optic chiasm, optic tracts, and lateral geniculate bodies of the thalami is more accurately depicted on MRI than computed tomography (CT). The size and shape of the optic canals are best assessed in the axial projection, while the size and shape of the optic nerves are best appreciated on coronal and oblique sagittal images. Many optic nerve tumors exhibit fusiform homogeneous enhancement (Figure 23). Unenhanced portions of optic nerve tumors may represent the sites of gliomatosis, rather than a true neoplasm. Biopsy is essential to make the correct diagnosis.^{23,24}

Figure 20 Perineural spread of squamous cell carcinoma. (a) This axial enhanced composite image shows bulging of the left side of the cavernous sinus and tumor extension into the preganglionic portion of the left trigeminal nerve (arrows). (b and c) Axial images. There is well defined edema and tumor infiltration into the left cerebral peduncle, pons, and middle cerebellar peduncle (arrows). The wide extent through the brainstem correlates with the long nuclei of the fifth cranial nerve

Figure 21 Facial neuritis and geniculate ganglionitis in a patient with Bell's palsy. Axial enhanced images. (a) Note the enhancement in the fundus of the right internal auditory canal with extension into the adjacent geniculate ganglion (arrow). (b) There is enhancement along the tympanic segment of the right facial nerve (arrow)

Figure 22 Enhanced images of viral trigeminal neuritis in a patient with trigeminal neuropathy. (a) There is enhancement along the preganglionic portion of the right trigeminal nerve (arrow). (b) This coronal view confirms the enhancement of the cisternal portion of the right trigeminal nerve (arrow). (c) The enhancement extends along the infraorbital division of the right maxillary nerve into the infraorbital groove (arrow)

Meningiomas are the most common optic nerve sheath tumors; they usually arise from the arachnoidal coverings of the optic nerve. Visual loss and optic atrophy are the usual presenting symptoms. Most cases are seen in middle-aged or elderly patients, more often in women. The tumor may be cuff-like surrounding the optic nerves or eccentrically located on only one side of the nerve. CT scans will often demonstrate calcifications and show typical postcontrast enhancement parallel to the length of the optic nerves. MR scans readily depict the irregular thickening along the optic nerves and spread into adjacent meninges on the postcontrast scans (Figure 24). Parallel optic cysts may be identified surrounding the optic nerve immediately distal to the meningioma. The process causes trapping of the cerebrospinal fluid in the subarachnoid space and can add to the mass effect and proptosis.^{23,25}

Optic neuritis is seen on MRI as focal or diffuse enlargement of the optic nerve associated with abnormal signal

intensities and enhancement (Figure 25). This is caused by immunological inflammation of the optic nerve, which affects the myelin sheaths with relative preservation of the axons. As optic neuritis is the initial manifestation of multiple sclerosis in about 20% of patients and may occur at some point in the disease in approximately 50%, the role of MRI in the evaluation of acute optic neuritis is changing. A multicenter trial was developed to assess the efficacy of corticosteroid treatment for acute optic neuritis. This study showed that the utility of MRI in establishing the diagnosis of optic neuritis was limited; however, with additional views of the cranial cavity, abnormal MRI scans could differentiate those patients who would later develop multiple sclerosis from those that would not. Thus, MRI is a predictor of multiple sclerosis as it can help to identify a subgroup of patients whose risk of developing the disease appears to be low and it can provide prognostic data about the development of multiple sclerosis after optic neuritis.^{23,26}

Figure 23 A 4-year-old boy with large left optic nerve glioma. There is a pear-shaped densely enhancing tumor mass in the left orbit causing mild proptosis. Note extension of the tumor into the orbital opening of the left optic nerve canal

The papilledema associated with the pseudotumor cerebri may be detected on CT or MRI scans as enlargement of the optic nerve sheaths. If severe, there is a reversal of the optic nerve head with bulging forward into the posterior wall of the globe. This phenomenon is more readily detected on CT than MRI because of the chemical shift artifact inherent to the MR

studies. There is some correlation between the severity of the visual loss and the detection of enlarged nerves with reversed nerve heads. Patients with more severe visual loss demonstrate more frequent and more severe reversal of the optic nerve head.²⁷

5.1 Optic Nerve Neuropathies

Isolated visual disturbances may result from a variety of optic nerve neuropathies, caused by radiation, chemotherapy, compressive phenomena, or ischemia.^{28–30} Radiation-induced optic neuropathy (RON) is a rare catastrophic complication of radiation therapy regimens used to treat a variety of neoplasms of the skull base, sella, and parasellar regions (Figure 26). There is typically a latency period of 6 to 36 months following treatment. Clinically, the nerve head may appear normal, but gadolinium-enhanced MRI will show patchy, linear, or confluent enhancement along the portions of the optic nerve, chiasm, or optic tract.^{25,28} These findings precisely correlate as the cause of delayed visual loss following radiation therapy. Treatment of RON with corticosteroids may be helpful, although optic atrophy may develop with permanent visual loss.²⁸

Compressive optic nerve neuropathies can be seen with a variety of lesions in the orbital apex [including Idiopathic Orbital Pseudotumor (IOP), thyroid ophthalmopathy with muscular hypertrophy, and edema causing compression of the intraocular portion of the optic nerve] or other systemic diseases with common orbital manifestations, such as sarcoidosis or Wegener's granulomatosis.^{29–36}

Compression of the optic nerve may occur as a result of cavernous carotid fistulae, arteriovenous malformations, or orbital varices. Such vascular anomalies may produce retrograde flow through the ophthalmic vessels, with subsequent dilatation of the orbital veins and passive congestion of the orbital tissues. This leads to progressive increases in the intraocular pressure and subsequent decreases in visual acuity

Figure 24 An 80-year-old female with left optic sheath meningioma. (a) Coronal enhanced view shows an enlarged left optic nerve with near complete enhancement of the lesion. (b) Axial enhanced MR scan shows the extent of the tumor in a 'railroad track' manner about the left optic nerve, with extension into the intracanalicular portion of the left optic nerve. Incidental note is made of a retinal banding procedure around the right globe

Figure 25 Right optic nerve neuritis in a 40-year-old female. (a) Axial enhanced MR scan showing no enlargement of the right optic nerve. There is enhancement along a major portion of the intraorbital part of the optic nerve. (b) Coronal enhanced scan showing the normal size but enhancing nerve in the right eye

leading to blindness. Spontaneous thrombosis of the ophthalmic veins occasionally occurs and may aggravate the mass effect within the apex of the orbit and the compressive neuropathy.^{23,33}

MRI will demonstrate the dilated ophthalmic veins, facial veins, and other regional venous structures along with enlargement of the cavernous sinus. Large edematous extraocular muscles and other periorbital structures may be identified. These findings are optimally seen with MRI, particularly as the addition of MR angiography allows for flow assessments along with the static morphologic changes. In some cases, conventional angiography may be required to make the definitive diagnosis, although most commonly this is used in conjunction with therapeutic interventional procedures.

6 VERTIGO AND HEARING LOSS

6.1 Dizziness and Vertigo

Dizziness is a common clinical complaint. It accounts for 1% of visits to US office-based physicians. Vertigo is a form of dizziness in which there is an illusion of movement (rotation, tilt, or linear translation). Vertigo occurs through an imbalance of tonic vestibular signals; consequently, it is a hallucination of movement and represents a symptom of a disturbed vestibular system.^{37,38}

The complete vestibular system comprises the end organs in the temporal bone, the vestibular components of the VIIIth cranial nerve, and the central connections in the brainstem. The end organs in the temporal bones are the cristae of the three semicircular canals, which respond to movement of the head, and the macula of the utricle, which records the position of the head. The semicircular canals record dynamic actions while the utricle records static function. Vertigo is subdivided into peripheral vertigo (caused by failure of the end organs) or central vertigo (caused by failure of the vestibular

lar nerves or central connections to the brainstem and the cerebellum.^{38,39}

6.2 Peripheral Vestibular Disorders

Patients with benign positional vertigo describe episodic vertigo lasting less than a minute, brought on by movements of the head and without other associated symptoms. There are no radiological findings in patients with benign positional vertigo.^{37,39}

In Meniere's disease, paroxysmal attacks of whirling vertigo are usually accompanied by nausea; the attacks are transient in nature, lasting a few hours but not days. The severe episodic vertigo is accompanied by tinnitus, fluctuating hearing loss, and a feeling of fullness in the affected ear or ears. Typically, hearing decreases and tinnitus increases during the attack. Hearing may improve between attacks in early stages of the disease. Generally, the hearing loss begins unilaterally and affects primarily the lower frequencies, with mid and high frequencies being affected in later stages of the disease.³⁷⁻³⁹

Meniere's disease is most common in middle age and may become bilateral in up to 50% of the affected patients. The etiology of Meniere's disease is a failure of the mechanism regulating the production and disposal of endolymph, resulting in recurrent attacks of endolymphatic hydrops. Since the endolymphatic duct and sac are the sites of resorption of endolymph, these structures play an important role in the pathogenesis of endolymphatic hydrops. The success of various surgical procedures in relieving the symptoms of Meniere's disease has led to great interest in using CT and/or MRI to evaluate the vestibular aqueduct and the endolymphatic duct and sac.³⁹⁻⁴¹

Unfortunately, there is no unanimity on the value of imaging in cases of Meniere's disease. Some investigators have used CT or MRI to evaluate the potential success of shunt surgery, based on showing patency of the vestibular aqueduct.^{39,41}

Figure 26 Parasellar and suprasellar Rathke's pouch cyst. (a) Fragile unenhanced scan showing the mass causing elevation of the optic chiasm. (b) Coronal enhanced scan at the level of the chiasm. Note that the non-enhanced cyst causes elevation and deformity of the optic chiasm. (c) Coronal enhanced scan at the level of the pituitary stock shows displacement of the stock to the right by the left parasellar mass

Other investigators, however, report that the size, shape, and patency of the vestibular aqueduct are of no value in predicting surgical results in shunt procedures or in predicting occurrence of bilateral disease.⁴⁰ MRI with its ability to detect the endolymphatic duct and sac, separate from the bony vestibular aqueduct, may offer more useful information than can CT.⁴¹ The value of CT and MRI may be in their ability to exclude associated infectious or neoplastic disease processes.^{38,39}

Vestibular neuronitis is a clinical diagnosis based on an aggregate of specific symptoms. The disease is characterized

by an acute onset of severe vertigo, lasting several days, followed by gradual improvement of several weeks. Hearing is typically unaffected. The history includes onset of vertigo following an illness such as an upper respiratory infection. Most patients become completely symptom free following central compensation.³⁹ Vestibular labyrinthitis is similar in that the disease presents with the acute symptoms of vertigo, but this disease is always associated with hearing loss. Labyrinthitis is usually viral in origin but may result from acute or chronic bacterial middle ear infections. Unlike viral labyrinthitis,

Figure 27 Tumor of the left internal auditory canal. Enhanced coronal image documents a linear enhancing tumor that fills the left auditory canal

labyrinthitis associated with suppurative ear disease may progress to develop partial or complete occlusion of the lumen of the affected labyrinth.^{38,39} Early on, the obstructed lumen may

be detected by MRI through loss of the signal intensity of the fluid contents. Later, more complete obliteration of all the labyrinthine structures occurs, leading to labyrinthitis obliterans, which is readily diagnosed on CT or conventional tomography.⁴²

With MRI, there may be postgadolinium enhancement of the labyrinthine structures or vestibular nerves during the acute or subacute stages of vestibular neuronitis and/or labyrinthitis.^{43,44} Such results must be interpreted with care, since sudden labyrinthine dysfunction may be caused by spontaneous hemorrhage or injury, which result in abnormal signal intensities within the labyrinthine structures secondary to the presence of blood products.⁴⁵

Diseases of the internal auditory canal and cerebellopontine angle are generally not characterized by severe attacks of vertigo but rather with intermittent dizziness and/or exacerbated periods of dizziness.^{37,39} A variety of benign or malignant tumors of the petrous temporal bone, such as paragangliomas, carcinomas, or metastatic tumors, may directly involve the labyrinthine structures, causing vertigo. Such processes are readily evaluated with MRI (Figures 27–29).

6.3 Central Vestibular Disorders

Lesions of the brainstem or cerebellum that result in central vertigo can readily be diagnosed by MRI. Vascular insufficiency in the vertebrobasilar circulation is a common cause of vertigo in patients over 50 years of age. Thrombosis of the

Figure 28 Meningioma of the right cerebellopontine angle. (a) Axial MR scan without contrast. The nearly isointense tumor can be seen to indent the left cerebellopontine angle. (b) Enhanced axial CT scan showing the full extent of the tumor mass. Note that the mass bends up to the level of the left fifth nerve (arrowhead). (c) Enhanced coronal image shows that mass to extend into the internal auditory canal, simulating an acoustic nerve tumor

Figure 29 Lipoma of the right cerebellopontine angle and vestibule. (a) Saggital unenhanced image shows the fat intensity mass in the cerebellopontine angle. (b) Coronal unenhanced images document the lesion in the right cerebellopontine angle with a small focus of a high signal in the region of the right vestibule. (c) Axial enhanced CT scan again shows the tumor masses both in the cerebellopontine angle and the vestibule. The patient complained of severe dizziness that was more likely related to the small lesion in the vestibule

labyrinthine artery or infarction of the lateral medulla from vertebral or posterior inferior cerebellar artery insufficiency may cause severe vertigo. The subclavian steal syndrome can cause a variety of symptoms, including vertigo.^{38,46,47} Such conditions can be carefully evaluated with MR angiography or conventional angiography of the posterior fossa vasculature.

A variety of other central nervous diseases may produce vertigo or dizziness. These include seizure disorders, multiple sclerosis, ataxic diseases, head injuries, or any cause for increased intracranial pressure. Vertigo may result from stroke and transient ischemic attacks may present as episodic dizziness.³⁹

Various metabolic disorders may result in dizziness. These include thyroid disorders, hyperlipidemia, diabetes, and hypoglycemia. Autoimmune diseases or diseases that affect the proprioceptive system may be the cause of vertigo. In many cases, the possibility of function neurotic symptoms must be considered in patients in whom no diseases can be found. Finally cervical spondylosis is thought to cause vertigo by disc

degeneration and narrowing of the disc space, which affects the nerves in close proximity, or by osteophyte formation, which compresses the blood vessels. In such cases, conventional radiographs and/or cross-sectional imaging procedures may be helpful.^{38,39,42}

6.4 Sensorineural Hearing Loss

Sensorineural hearing loss may be sudden, fluctuating, or progressive. Sudden sensorineural hearing loss is a manifestation of viral infections, vascular occlusive diseases, or inner ear membrane ruptures.⁴⁸⁻⁵² As discussed above, there may be vertigo associated with these conditions, which would help to define whether the lesion is peripheral or central. In order to discriminate idiopathic or viral infections from other causes of sensorineural hearing loss, auditory brainstem responses and gadolinium enhanced MRI may be utilized.⁴⁸⁻⁵⁰ Patients with cochleitis or cochlear nerve neuritis typically have abnormal

auditory brainstem responses and may be helped by a tapering course of oral corticosteroids.^{49,50} Whether gadolinium enhanced MRI shows enhancement of the cochlear nerve or cochlea is not a helpful indicator for or against using corticosteroid therapy. However, one study suggests that sudden deafness associated with MRI changes is more difficult to cure with steroid therapy than that without associated MRI changes.⁴⁹

Fluctuating neurosensory hearing loss is a difficult disease to assess properly. The audiometric examination does, of course, indicate the level of dysfunction but not the likely cause. In patients where MRI indicates large vestibular aqueducts (apertures greater than 4 mm), this may indicate a fluctuating frequency loss more often than low frequency loss. Fluctuating sensorineural hearing loss resulting from an enlarged vestibular aqueduct appears to be more common in children and young adults, which is an important point in differentiating this disease from Meniere's disease in which the majority of patients are middle aged or older. The vestibular aqueduct of patients with Meniere's disease may be small rather than large.^{38,39}

There is speculation on the causes of a sudden drop in hearing in patients with large vestibular aqueducts.⁵³ Two possible causes are reflux of hyperosmolar fluid from the endolymphatic sac to the inner ear and rupture of the membranous labyrinth or a perilymphatic fistula caused by transmission of intracranial pressure to the inner ear through the enlarged vestibular aqueduct. It is well recognized that patients sustaining relative minor head trauma, or patients who are subjected to extreme barotrauma (scuba diving), may have aggravated episodes of hearing loss. Consequently, it may be worthwhile to image the temporal bones in order to detect enlarged vestibular aqueducts and thus advise the patients or their parents of the dangers of contact sports or activities that entail extreme barometric pressure changes. The imaging findings must be correlated with audiometry, since the fluctuating sensorineural hearing loss of large vestibular aqueduct patients does not resemble the low frequency changes characteristic of Meniere's disease which may also be associated with fluctuating hearing loss.^{54,55}

The pathophysiologic basis of disease in patients with isolated large vestibular aqueducts may differ from that in patients whose large aqueducts are associated with other inner ear malformations. Patients with complex inner ear malformations may be subject to recurrent episodes of meningitis and/or the 'gusher' syndrome, resulting in a dead ear at the time or surgical intervention such as a stapedectomy.^{52,54}

Asymmetric sensorineural hearing loss or gradually declining unilateral sensorineural hearing loss is a common symptom that may be ascribed to a variety of pathologic processes. Initial evaluation attempts to find the site of the lesion (i.e. cochlear or retrocochlear). All retrocochlear lesions are associated with an abnormal auditory brainstem response, which is often obtained prior to an imaging study. Whether auditory brainstem response testing should be eliminated as a cost-saving measure is a subject of considerable debate. It seems unlikely that clinicians will refer patients directly to MRI without at least preliminary audiometric and/or auditory brain response testing.^{48,50,56}

A complete MR study of the head should be performed in addition to the studies of the internal auditory canal and temporal bones. The MR examination should include complete evaluation of the central nuclei in the brainstem as well as the

auditory pathways extending upwards into the cerebral hemispheres.⁷ Whether or not gadolinium contrast enhancement is routinely utilized depends on a variety of factors including coil size, field of view, field strength, and pulse sequences. CT is diagnostic in lesions 1–1.5 cm or greater in diameter but does not readily detect small brainstem lesions such as infarctions or demyelination.^{7,56}

Degenerative Disk Disease Studied by MRI

Michael T. Modic

Cleveland Clinic Foundation, OH, USA

1 INTRODUCTION

Degeneration of the intervertebral disk complex is a process that begins early in life and is a consequence of a variety of environmental factors as well as normal aging. The pathophysiology of this disorder is complicated and poorly understood. It has been stated¹ that degeneration as commonly applied to the intervertebral disk covers such a wide variety of clinical, radiologic, and pathologic manifestations as to be really 'only a symbol of our ignorance'.

It is estimated that low back pain affects 5% of the adult population each year and that the lifetime incidence of LBP in adults is 60–80%.² Fortunately, the natural history of back pain is such that the vast majority of back pain sufferers improve with little or no medical intervention; only 14% of patients have episodes of pain lasting more than 2 weeks.³ Despite the self-limited nature of most LBP, the total societal costs of LBP have been estimated at US\$16–100 billion annually,² and, as back pain is the second leading cause of physician visits among American adults, it is estimated to account for more than US\$10 billion in direct medical care costs each year.⁴ Much of the direct cost of treating patients with LBP is related to diagnostic tests;⁵ it is estimated that MRI alone contributes US\$2 billion dollars in direct medical care costs (Modic MT, 1993, projected estimate).

The sequelae of disk degeneration remain among the leading causes of functional incapacity in both sexes and are an all too common source of chronic disability in the working years. However, by the age of 50 years, 85–95% of adults show evidence of degenerative disk disease at autopsy;⁶ thus the jump from identifying an anatomic derangement to proposing a symptom complex must be made with caution, since to date only a moderate correlation has been found between imaging evidence of disk degeneration and symptomatology.⁷ There is no unifying theory regarding the cause of disk degeneration. It is likely that degeneration and aging are multifactorial processes that encompass a wide spectrum of changes and sequelae. Nevertheless, in patients in whom surgical therapy is planned, or where the diagnosis remains elusive and patient treatment and outcome is dependent upon a more definitive diagnosis, imaging studies are an important component in the evaluation of patients with symptoms of disk disease.

2 MORPHOLOGY

The contrast sensitivity and multiplanar imaging capability of proton magnetic resonance (MR) place this modality in a position to provide a unique noninvasive means of imaging

intervertebral disks. The implementation of surface coil technology,⁸ cardiac gating,⁹ gradient refocusing,¹⁰ paramagnetic contrast agents,¹¹ saturation pulses,¹² gradient echo volume imaging, turbo (fast) T_2 -weighted spin echo sequences, and magnetization transfer techniques continue to refine the capability of MRI for degenerative disk disease. When a combination of imaging planes and pulse sequence parameters is used, the anatomy of the intervertebral disk (Figure 1), spinal nerves, dural sac, and adjacent structures can be clearly depicted. From a morphological aspect, MRI may be the most accurate means of evaluating the intervertebral disk. Accordingly, most research to date has been directed clinically towards optimizing anatomic image display in a fashion similar to that of computerized tomography (CT) for assessment of disk contour.^{13–19} Unlike CT and conventional radiography, however, which are dependent on information related to electron density, proton MR signals are influenced by the T_1 and T_2 relaxation times, and by proton density, providing greater tissue contrast. Thus the role of this technique may go beyond gross anatomic appraisal to actual tissue characterization of pathology and biochemical change.²⁰

The relationship among the vertebral body, endplate, and disk has been studied^{21–24} using both degenerated and chymopapain-treated disks as models. Signal intensity changes in vertebral body marrow adjacent to the endplates of degenerated disks are a common observation in MRI. Work using T_2 -weighted spin echo sequences²⁰ further suggests that MRI is capable of detecting changes in the nucleus pulposus and annulus fibrosus relative to degeneration and aging based on a loss of signal presumed to be secondary to known changes in hydration that occur within the intervertebral disk (Figure 2). However, the correlation is not straightforward, since differences in signal intensity appear to be somewhat exaggerated for the degree of water loss noted with degeneration (about 15%).²⁵ At present the role that specific biochemical changes (proteoglycan ratios, aggregating of complexes) play in the altered signal intensity is not well understood. In fact, the important factor may not be the total quantity of water but the state that the water is in. Sodium images suggest that the T_2 signal intensity in the disk tracks the concentration and regions of high glycosamino glycans (GAG) percentages. Thus it seems likely that the health and status of the proteoglycans determine the signal intensity.

The vacuum phenomenon within a degenerative disk is represented on spin echo images as areas of signal void.²⁶ Gradient echo sequences demonstrate this better than do conventional spin echo sequences, plain radiographs and CT. This is due to the magnetic susceptibility effects caused by the intradiskal gas collection. Whereas the presence of gas within the disk is usually suggestive of degenerative disease rather than an infected process, spinal infection may (rarely) be accompanied by intradiskal or intraosseous gas.²⁷ A gas density cleft within a transverse separation of the vertebral body appearing in extension and disappearing in flexion is characteristic of the vacuum phenomenon within a region of ischemic vertebral collapse. Rarely, the phenomenon has been identified with vertebral body neoplasms such as multiple myeloma.^{28–32}

Hyperintense intervertebral disks are not an infrequent finding on T_1 -weighted MR images of the spine, and it has been suggested³³ that the relatively 'bright' intervertebral disk may reflect diffuse abnormality and loss of normal signal in the

Figure 1 Axial L3-L4 disk: (a) and (b) are normal. Axial T_1 -weighted spin echo (500/17), and T_2 -weighted spin echo (2000/90) images through the axial midplane of the intervertebral disk. On the T_1 -weighted axial image (a) the disk has a homogeneous soft tissue signal intensity. On the T_2 -weighted image (b) three distinct components of the disk can be identified: first, a decreased signal intensity is noted in the outer annulus and ligamentous region; second, the inner annulus has a slightly increased signal intensity, and third, the region of the nucleus pulposus has the highest signal intensity consistent with the highest concentration of proteoglycans

marrow of the adjacent vertebral bodies. Calcification has usually been described on MR images as a region of decreased or absent signal. The loss of signal is attributed to a low mobile proton density as well as, in the case of gradient echo imaging, to its sensitivity to the heterogeneous magnetic susceptibility found in calcified tissue.

There is, however, variability of signal intensity of calcium on various sequences; the type and concentration of calcification are probably important factors. Multiple examples of a hyperintense signal on T_1 -weighted spin echo images in areas that contain calcification on CT have been reported in the literature. These hyperintensities have been attributed to the paramagnetic effects of methemoglobin,³⁴⁻³⁶ melanin,³⁷ and trace elements,^{38,39} as well as to the T_1 -shortening effects of lipids and cholesterol,⁴⁰ proteins,^{41,42} and laminar necrosis associated with infarction and calcification.⁴³⁻⁴⁷ Focal or diffuse areas of hyperintensity on T_1 -weighted spin echo sequences may also be encountered in the intervertebral disk. Hyperintensities that are affected by fat-suppression techniques have also been noted within intervertebral disks.⁴⁸ These are presumably related to areas of ossification with formation of a lipid marrow in the ossified disk space; they also appear calcified on conventional studies.

3 SEQUELAE OF DISK DEGENERATION

Disk herniation, especially in the lumbar and thoracic regions, is probably better depicted by MRI than by other mod-

alities.^{14-19,49,50} It is, again, important to bear in mind that not all morphological changes are a cause of symptoms. In a prospective study of individuals who never had low back pain, sciatica or neurogenic claudication,⁵¹ one-third of the subjects were found to have substantial abnormalities. In patients who were less than 60 years of age, 20% had a herniated nucleus pulposus. In the group that was 60 years or older, findings were abnormal on 57% of the scans. Thirty-six per cent of the subjects had a herniated nucleus pulposus, and 21% had spinal stenosis. More recent studies^{52,53} have confirmed the observation that disk bulges and protrusions are common findings on MRI in the asymptomatic population. These latter studies, however, suggest that frank disk extrusion is rare; a disk bulge was observed to be age related, but disk protrusion was not.

Multidimensional imaging allows the direct acquisition of orthogonal views covering long segments of the spine, without requiring secondary reconstructions. Alternatively, three-dimensional datasets can be acquired with or without contrast, which allows multiplanar reformation with variable partition thicknesses for improved overall spatial resolution and reduced examination times. The outer annulus-posterior longitudinal ligament (PLL) complex can usually be seen as an area of decreased signal relative to the inner annulus-nucleus pulposus, which helps in characterizing the type of herniation (protrusion, extrusion and/or sequestration).⁵⁴ This ability to characterize and differentiate the various subgroups of disk herniation has been proposed to have certain diagnostic and therapeutic ramifications, particularly in the lumbar region.

Figure 2 Spin echo and gradient sagittal images. (a) Intermediate spin echo (2000/20). (b) T_2 weighted spin echo (2000/90). (c) FLASH (50/13/10 degrees). (d) FLASH (50/13/60 degrees). (b) There is decreased signal intensity in the L4-L5 and L5-S1 disk, consistent with degeneration. The L2-L3 and L3-L4 disks have a normal signal intensity. The signal intensity changes consistent with degeneration are not as well appreciated from sequences (a), (c) and (d). (Reproduced with permission from *Magnetic Resonance Imaging of the Spine*, 2nd edn, Chap. 2, p. (52, Fig. 2-14)

Abnormal disks can be classified as an anular bulge or herniated (protruded, extruded, or free fragment). Concurrently, herniated disk disease should be described by contour, size, location, and presence or absence of enhancement.

4 BULGE

An anular bulge is a result of disk degeneration with a grossly intact, albeit lax, anulus, usually recognized as a generalized extension of the disk margin beyond the margins of the adjacent vertebral endplates, regardless of the signal of the interspace. An index of disk bulging using sagittal anatomic

sections from 149 lumbar disks⁵⁵ has been studied. The largest disk bulgings were always associated with radial tears of the anulus, which contradicts the previously held concept that the anulus fibrosus remains intact with a bulging disk.

Some investigators would recognize the anular tear as an intermediate category between bulge and herniation. The significance of the anular tear, however, remains extremely unclear; it is perhaps best considered as a sequela of disk degeneration rather than as a discrete category that may imply some type of clinical significance. On nonenhanced T_2 -weighted MR images anular tears are best appreciated as an area of high signal extending into the area of decreased signal of the anulus-ligamentous complex (Figure 3).

Figure 2 continued

5 LUMBAR DISK HERNIATIONS

Obviously some degree of anular disruption is an intrinsic component of any disk herniation.

A protrusion represents herniation of nuclear material through a defect in the anulus, producing a focal or broad-based extension of the disk margin. The extension is less than that which occurs with an extrusion. At least some fibers of the overlying anulus and PLL remain intact, and the disk is described as 'contained'. The signal intensity of the parent nucleus is usually decreased.

The next two categories, extrusion and sequestration, represent herniations that are no longer contained by the overlying anulus and ligament (Figure 4). In an extrusion, nuclear material becomes an anterior extradural mass that remains attached to the nucleus of origin, often via a high-signal pedi-

cle on the T_2 -weighted image. The signal intensity of the extruded portion may be increased or decreased. The disk usually appears contained by the PLL and remaining contiguous portions of the anulus, which show up as curvilinear areas of decreased signal.

The term 'free fragment' or 'sequestered disk' refers to disk material external to the anulus fibrosus and no longer contiguous with the parent nucleus. A frequent finding with both extruded and free fragments is the presence of a high signal intensity extradural defect often surrounded by a curvilinear area of decreased signal that is distinct from the interspace of origin.

Whereas all of the foregoing has become a part of our clinical lore, it is not at all clear whether these findings are clinically relevant. It has been proposed, for example, that differentiating between various degrees of herniation is critically

Figure 3 Sagittal T_2 -weighted spin echo image (2000/90) through a cadaveric spine. Note the loss of signal intensity at the L4-L5 disk and the region of high signal extending into the anulus-ligament complex (arrow). This represents an annular tear. (Reproduced with permission from *Magnetic Resonance Imaging of the Spine*, 2nd edn, Chap. 3, p. 96, Fig. 3-16)

important; yet the reality of the situation is that any disk herniation most likely represents a spectrum or continuum rather than a discrete entity with specific clinical relationships. One may view the continuum of herniated disk disease as starting with anular disruption, proceeding to a small focal herniation that does not break through the anulus-ligamentous complex, and winding up as a frank herniation (extrusion) that does indeed dissect through the anulus-posterior ligamentous complex.

Traversing nerve roots within the thecal sac above a particular level of impingement from a herniated disk or stenosis have been noted to be enlarged compared to the contralateral side. This may be a reflection of nerve root edema. Enhancement of traversing nerve roots within the thecal sac has also been reported⁵⁶ on MRI, the majority of cases being associated with focally protruding disk pathology. A significant number of these patients, however, had isolated enhancement of multiple nerve roots without significant associated

anatomic pathology. The mechanism of such enhancement may be related to the blood-nerve barrier of this spinal nerve root, which is altered by compression.⁵⁷ It has also been suggested that the enhancement may be related to the vascular anatomy as a variation of normal, rather than as a pathologic reaction.⁵⁸

In a prospective evaluation of surface coil MRI, CT, and myelography for lumbar herniated disk disease and canal stenosis¹⁶ there was 82.6% agreement between MRI and surgical findings regarding type and location of disease, 83% agreement between CT and surgical findings, and 71.8% agreement between myelography and surgical findings. In another study,⁵⁹ the accuracy of CT, myelography, CT-myelography and MRI for lumbar herniated nucleus pulposus was compared prospectively in 59 patients, all of whom underwent surgical exploration. MRI was the most accurate (76.5%), CT-myelography next (76%), and then CT (73%) and myelography (71%). The false-positive rate was lowest for MRI, at 13%, followed by myelography and CT.⁵⁹ Similar data from a carefully controlled prospective study in Wisconsin⁶⁰ suggest the same equivalence for plain CT, CT-myelography, and MRI.

The natural history of lumbar disk herniation has engendered recent interest and MRI has been an excellent tool for these investigations. Multiple studies have demonstrated that the size of the disk herniation can change with time, and studies of patients treated conservatively have demonstrated that the majority will show a reduction in disk herniation size of 30–100%. The larger herniations show the most significant decrease in size. A resulting impression has also been that patients who do well conservatively will show this reduction in herniation size, yet the correlation of disk changes with time and symptoms resolution has not yet been carefully worked out.

As part of a long term natural history study, patients with acute radiculopathy were evaluated clinically and with contrast enhanced MRI to determine if there was a correlation between presenting symptoms and the type, size, location and enhancement of the disk herniations at presentation. In this group, 72% had a herniated disk at one or more levels at presentation. There was excellent agreement between MRI and clinical findings for level and size, but no correlation of pain and disability with disk size, type or enhancement. At the 6-week follow-up, 36% of large herniated disks demonstrated a significant reduction in size (Figure 5), but there was no difference in clinical outcome based on disk size, change, or type. At 6 months, 60% of herniated disks had reduced significantly in size, but again there was no correlation of pain and disability with disk size, change, or type.

Enhancement of herniated disk was almost a constant feature. The degree of enhancement was variable and probably related to granulation tissue which develops around and through herniated disk. The granulation tissue response itself may comprise a fair percentage of the herniated disk mass. One possible explanation for the change of a disk with time then is that the granulation tissue undergoes cicatrization and retraction, a normal phenomenon for reparative tissue.

Although less common than lumbar or cervical herniations, thoracic herniations have been noted more frequently with the advancement of imaging techniques.¹⁹ A higher prevalence of

Figure 4 L4–L5 disk herniation. (a) Pre- and (b) post-contrast sagittal T_1 -weighted spin echo images demonstrate an extradural mass at the L4–L5 disk level. Axial T_1 -weighted spin echo (500/17 images) before (c) and after (d) contrast show the peripheral enhancement of disk material, which is also appreciated on the sagittal images. The enhancing areas of granulation tissue contribute to the overall size of the mass. (Reproduced with permission from *Magnetic Resonance Imaging of the Spine*, 2nd edn, Chap. 3, p. 102, Fig. 3-26)

asymptomatic morphologic change is also present in the thoracic spine.

Symptomatic cervical disk herniations are most common in young patients (third and fourth decades) and frequently occur without recognized trauma. In a prospective study of patients with no symptoms of cervical disease,⁶¹ 10% of subjects less than 40 years of age had a herniated nucleus pulposus and 4% had foraminal stenosis. Of the subjects who were older than 40 years of age, 5% had a herniated nucleus pulposus, 3% a bulging disk, and 20% foraminal stenosis. Narrowing of the disk space, degeneration of a disk, spurs, or compression of the cord were noted at one or more levels in 25% of the subjects less than 40 years of age and in almost 60% of those who were older than 40.

Cervical disk herniation, especially when central or large, is well appreciated on routine sagittal and axial MR images.

Again, thin slices (3 mm or less) are critical for accurate diagnosis. This may necessitate the use of three-dimensional volume sequences with partitions of 2 mm or less and/or reconstructions in other planes. The T_2 signal intensity of intervertebral disks in the cervical region is not as helpful as that in the lumbar region for identifying the presence or absence of degeneration. Cervical disk herniation is usually identified on sagittal images as an anterior or anterior–lateral extradural defect that may indent or compress the cervical cord. In a prospective study to compare the accuracy of surface coil MRI with metrizamide myelography (MM) and CT with metrizamide (CTM),¹⁷ there was surgical agreement in 74% of patients with surface coil MRI, 85% with CTM, and 67% with MM. When surface coil MRI and CTM were used jointly, 90% agreement with surgical findings was seen, and when CTM and MM were used jointly there was 92% agreement. In gen-

Figure 4 continued

eral, surface coil MRI was as sensitive as CTM for identifying disease level, but not as specific for type of disease.

In another study comparing MRI and CT, plain film myelography, and CT-myelography in 35 patients operated on for cervical radiculopathy and myelopathy,⁶² MRI correctly predicted 88% of the surgically proved lesions. The corresponding rates were 81% for CT myelography, 58% for plain myelography, and 50% for CT.

Although we would maintain that most evaluations of the cervical spine for extradural disease can be done in an adequate fashion using spin echo T_1 -weighted sagittal and axial images, the introduction of fast gradient echo images with small flip angles (less than 15°) has improved the accuracy of the examination by increasing the conspicuousness of extradural defects. Recent work⁶³⁻⁶⁵ has confirmed the value of this technique. This capability, coupled with the potential of utilizing very short TR s (50 ms or less), has provided the stimulus for using volume imaging in the evaluation of extradural disease, in the hope of shortening the examination time and decreasing slice thickness.

The disadvantages of gradient echo imaging relate to problems with field inhomogeneity and contrast detectability of pathologic processes within the cord itself. Furthermore, depending upon the echo time, the ability accurately to characterize morphologic defects, foraminal narrowing, and bony ridges is inferior to that for viewing bone by CT.

An adjunct to conventional MRI in evaluating degenerative disk disease is the utilization of gadolinium diethylenetriamine-pentaacetic acid (Gd-DTPA). Studies with virgin disks and

postoperative disk herniation¹¹ indicate that it is the most accurate means of separating epidural fibrosis and disk tissue. There is consistent enhancement of peridiskal fibrosis early (less than 15 min after injection), and variable enhancement occurs in herniated or degenerated parent disks late (30 min after injection). Enhancement of intervertebral disks does not appear to occur in the normal state and is probably a sequela of the degenerative process.^{11,66} Thus it seems likely that Gd-DTPA may play a role in identifying the sequelae of degenerative disk disease by enhancing the reactive granulation tissue that forms secondary to disruption of the disk and associated structures.

In addition to changes within the disk, including herniation, secondary changes are noted both in animal models and in humans following disk degeneration. The stability of a motion segment depends on the integrity of all its components. Diseases occurring in this area are circumferential, with that in one joint affecting another, and degeneration of one disk leads to a loss of disk height and forces the facet joints into malalignment, so-called 'rostrorocaudal subluxation'. This leads to increased biomechanical forces at the facet joint with increasing joint relaxation and instability, secondary facet and arthritic changes, and potential fractures. Similarly, abnormal movements allowed by disk degeneration and facet changes add stress to the posterior ligaments and can result in hypertrophy. A vicious degenerative cycle is established which includes degenerative disk disease, facet arthrosis, ligamentous and capsular hypertrophy, spinal instability, and lumbar stenosis.⁶⁷

Figure 5 L3–L4 disk herniation. (a) Pre- and (b) post-contrast axial T_1 -weighted spin echo images through the L3–L4 disk in a patient who presented with the onset of acute right-sided radiculopathy. A moderate sized extradural mass is identified on the right which shows peripheral enhancement following the administration of contrast. (c) (d) Axial T_1 -weighted spin echo (500/17) images at the same level as (a) and (b) following 6 weeks of conservative management. There is a marked reduction in the size of the extradural mass, although there is still some enhancement in this region

6 SPINAL STENOSIS

Spinal stenosis results from an overall diminution of the spinal canal, lateral recesses, or neural foramina. It occurs more commonly in the lumbar and cervical regions. The symptoms are usually a reflection of the compressive pathology.

In the lumbar spine, central stenosis tends to occur at multiple levels but is most frequent and usually most severe at the L4–L5 level, where it may occur alone.

The transverse and sagittal dimensions of the central neural canal are best depicted by integrating orthogonal (e.g. axial and

sagittal) planes. Gradient echo images with low flip angles or more T_2 -weighted spin echo sequences provide the best views of thecal sac dimensions by furnishing a gray-scale inversion of the cerebrospinal fluid and extradural elements.^{63,64}

Peripheral stenosis is best appreciated on T_1 -weighted images, which maintain the separation between neural structures and epidural fat quite well. The signal intensity between neural elements and fat is less well seen on more T_2 -weighted and gradient echo images, although bony overgrowth can be identified.

In the cervical spine degenerative changes affect all major spinal articulations, including the intervertebral disks, apophy-

seal joints, ligamentous connections between vertebral bodies, and the vertebral bodies themselves.

The suggestion has been made⁶⁸ that myelopathy or stenosis is associated with an average canal diameter of less than 12 mm. Care must be taken, however, when using gradient echo images since the degree of spinal narrowing can be overestimated because of susceptibility effects. Another method suggested for determining cervical spinal stenosis⁶⁹ is the vertebral body/canal ratio, which has been suggested to correct for body size. A spinal canal/vertebral body ratio of less than 0.82 would indicate significant cervical spinal stenosis. MRI and myelographic CT studies appear to be equivalent in measuring the degree of cord compression. There may be a correlation between compression and the amount of neurologic dysfunction.⁷⁰

Although there are no good studies to indicate that MRI has led to improved therapeutic choices, there is at present sufficient evidence to suggest that MRI is adequate for most therapeutic planning to allow physicians to stop further testing, obviating the need for a myelogram or CT scan.^{71,72}

7 FACET JOINTS

Although facet arthrosis constitutes an important cause of acquired lumbar stenosis, degenerative change can occur independently of it and may be a cause of low back pain and radiculopathy.^{67,73}

On MRI the facet joints are best evaluated by visually integrating sagittal and axial images. Again, osteophytes are easier to identify on gradient echo or spin echo images with long relaxation times. Those that contain marrow are also better demarcated than are those that are sclerotic, which can be confused with the adjacent capsular ligamentous structures. Altered signal intensity in bone marrow consistent with fatty replacement has also been reported to be commonly associated.⁷⁴ The articular cartilage can be directly visualized on both T_1 and T_2 -weighted spin echo images, but thinning is difficult to measure accurately because of variable axial obliquity and chemical shift artifact from the adjacent facet. Gradient echo examinations have demonstrated that they provide better conspicuousness of the articular cartilage itself as distinct from adjacent osseous structures.

In summary, degenerative disk changes appear to be a normal consequence of the aging process. MRI is an excellent modality for depicting them. However, the clinical relevance of these morphologic changes remains to be established and the value of MRI as a prognostic indicator for patient outcome needs to be studied more fully. At the present time, one can clearly recommend MRI as the single best presurgical decision-making tool, but its role in the evaluation of patients who are going to be treated in a conservative fashion appears to be much more limited.

Biographical Sketch

Michael T. Modic received his M.D. degree from Case Western Reserve School of Medicine in 1975. He completed his residency in radiology and fellowship in neuroradiology at the Cleveland Clinic Foundation. He spent a year as assistant professor of Radiology and as a staff neuroradiologist at University Hospitals in Cleveland from 1979–1980 and in 1980 returned to the Cleveland clinic as a staff neuroradiologist. In 1982 he was appointed head of the section of Magnetic Resonance. In 1985 he returned to Case Western Reserve School of Medicine/University Hospitals as Director of Magnetic Resonance and Neuroradiology, positions he held through 1989. During that time he also held the rank of Professor of Radiology, Neurology, and General Medical Sciences. In 1988 he was given a joint appointment as Professor of Neurosurgery as well. In 1989, Dr. Modic returned to the Cleveland Clinic Foundation as Chairman of Radiology and in 1993 was appointed as Professor of Radiology, Ohio State University. Dr. Modic has served on the Editorial Boards of the journals *Radiology*, *American Journal of Neuroradiology*, *Neurology*, *Magnetic Resonance in Medicine*, and *Magnetic Resonance Imaging*. He has served as a member of the Board of Trustees of the Society of Magnetic Resonance in Medicine and Board of Directors of the Society of Magnetic Resonance Imaging. He was President of the Society of Magnetic Resonance in Medicine for the 1992–1993 year and was the recipient of the Society Gold Medal in Clinical Science for his research activities related to the spine in 1991. He is co-author of the text 'Magnetic Resonance Imaging of the Spine' which is in its second edition and is the author or co-author of over 125 peer reviewed articles related to neuroradiology.

Eye, Orbit, Ear, Nose, and Throat Studies Using MRI

Mahmood F. Mafee

University of Illinois at Chicago, Chicago, IL, USA

1 MRI OF THE EYE

1.1 Introduction

The eye consists of three primary layers: (1) the sclera, or outer layer, composed primarily of collagen-elastic tissue; (2) the uvea or middle layer, a richly vascular and pigmented tissue consisting of the iris, ciliary body, and choroid; and (3) the retina or inner layer, the neurosensory stratum of the eye.¹ The Tenon's capsule (bulbar fascia) is a fibroelastic membrane that covers the sclera and envelops the eyeball. Tenon's capsule encloses the posterior four-fifths of the eyeball separating it from the orbital fat. Tenon's capsule is separated from the sclera by the potential Tenon's space.^{2,3}

1.2 Anatomy of the Globe

1.2.1 Anterior and Posterior Segments of the Globe

The ciliary body and the iris divide the globe into an anterior and a posterior segment. The anterior segment which includes the anterior and posterior chambers is the space lying between the cornea and the crystalline lens. The posterior (vitreous) segment contains the vitreous chamber (body), which acts as a biologic shock absorber. The vitreous chamber is a gel-like, transparent, extracellular matrix, composed of a meshwork of 0.2% collagen fibrils interspersed with 0.2% hyaluronic acid polymers, 98–99% water, and small amounts of soluble protein.^{4,5}

1.2.2 Lens

The lens is one of the least hydrated organs of the body containing only 66% water.⁵ The remainder is composed of long, thin cells (lens fibers) whose main cytoplasmic content is protein.

1.2.3 Sclera

The sclera, the outer, white, leathery coat of the globe is primarily composed of cellular bundles of collagen. Its external surface lies adjacent to Tenon's capsule. Its internal surface blends with the uveal tissues.

1.2.4 Uvea (Iris, Ciliary Body and Choroid)

The uvea lies between the sclera and retina and provides vascular supply to the eye and regulates ocular temperature. The choroid is a portion of the uvea that lies between the sclera and the retinal pigment epithelium (RPE). The ciliary body is a direct anterior continuation of the choroid, and the iris is a further extension of the ciliary body itself.

1.2.5 Retina

The external surface of the retina is in contact with the choroid and the internal surface is adjacent to the vitreous body; posteriorly, the retina is continuous with the optic nerve. Grossly the retina has two layers: (1) the inner layer is the sensory retina, composed of photoreceptors, first and second order neurons (ganglion cells) and neuroglial elements and (2) the outer layer is the RPE, which consists of a single lamina of cells whose nuclei are adjacent to the basal membrane of the choroid, the so-called Bruch's membrane.

1.3 MRI Anatomy of the Globe

The globe is unique in that it contains the most (vitreous) and the least (lens) water concentration of all the tissues in the body.^{4,5} The eye is an ideal organ to be evaluated by MRI because the wide variations in water content produce different water proton relaxation times of the various tissues. The eye can be imaged using head coil or surface coil. Images obtained with surface coil provide better spatial resolution. A routine MRI of the eye usually includes single echo short repetition time (TR), short echo time (TE) (TR/TE , 400–600/20–25 ms), sagittal and axial views and an axial view SE double echo (TR/TE , 2000/20–25; 70–100 ms) pulse sequences. Following the intravenous (i.v.) administration of gadolinium diethylenetriaminepentaacetic acid (Gd-DTPA), single echo, short TR , short TE images in axial and other views are obtained with or without fat suppression techniques. The section thickness for MRI of the eye should be 3 mm. The normal lens has long T_1 and short T_2 relaxation properties on MRI (Figure 1). The nucleus of the lens has both lower water content and shorter T_2 than the cortex of the lens. The sclera has a low signal intensity on various pulse sequences which is probably related to the short T_2 caused by a greater proportion of bound water.⁵ Differentiation of individual layers of the retina, choroid, and posterior hyaloid membrane is impossible by MRI in the normal eye; however, in pathological conditions, detachment of different layers of the eye can be visualized on MR images.

1.4 MRI of Ocular Pathology

MRI has served as an important diagnostic method in ophthalmology for the last decade.^{2,6–14} Excellent contrast between various normal structures and high sensitivity in detection of pathologic states is due to the intrinsic differences in proton density and in proton relaxation times.^{2,4}

1.5 Posterior Hyaloid, Retinal, and Choroidal Detachment

The posterior hyaloid space is a potential space between the posterior hyaloid (vitreous) membrane and the sensory retina. The posterior hyaloid membrane is thin and is invisible on MRI. It becomes visible when blood or other fluid fills the potential posterior hyaloid space. On MRI, a detached posterior hyaloid membrane is seen as a thin membrane within the globe, in front of the optic disk.

Retinal detachment results from separation of the sensory retina from the RPE with accumulation of fluid in the potential subretinal space.

Figure 1 Normal MRI anatomy of the eye and orbit. Sagittal PW (top) and T_2W (bottom) MR images. Ac = anterior chamber, EL = eyelids, FB = frontal bone, IO = inferior oblique muscle, IR = inferior rectus muscle, L = lens, Lc = lens capsule, LPS = levator palpebra superioris, MA = maxillary antrum, OA = ophthalmic artery, ON = optic nerve, OO = fibers of the orbicularis oculi muscle, SOV = superior ophthalmic vein, SR = superior rectus muscle, STP = superior tarsal plate, Tc = Tenon's capsule

Since the retina is very thin, it cannot be directly visualized on MRI scans. However, it may be shown when it is outlined by significant contrast differences between the subretinal effusion and the vitreous chamber. On axial MRI, the detached retina is seen as a V-shaped structure, with its apex at the optic disk and its extremities toward the ora serrata just behind the ciliary body, where the sensory retina ends. On coronal MR scans, retinal detachment appears as a characteristic folded membrane. The subretinal exudate is rich in protein, therefore has higher MR signals than the vitreous cavity on T_1 - and often on T_2 -weighted MR images.

Choroidal detachment results from the accumulation of fluid (serous) or blood (hemorrhagic choroidal detachment) within the potential space between the choroid and the sclera. MRI is an excellent technique in the evaluation of choroidal detachment, particularly when ultrasonography or computerized tomography (CT) in conjunction with the clinical examination have not provided sufficient information. Serous choroidal detachment appears as a semilunar or ring-shaped area of higher MR signal than vitreous on T_1 - and T_2 -weighted MR images.⁹ The appearance of choroidal detachment on MR images may be confused with retinal detachment. However, choroidal detachment is often restricted by the anchoring effect

of the vortex veins and short posterior ciliary arteries. This restriction results in a characteristic appearance in which the leaves of the detached choroid, unlike the detached retina, frequently do not extend to the region of the optic disc.

The MRI appearance of hemorrhagic posterior hyaloid, retinal and choroidal detachments varies with the age and the degree of organization of the hemorrhage. A hematoma less than 48 h old usually appears iso- to slightly hypointense relative to the normal vitreous body on T_1 -weighted (T_1W) and proton-weighted (PW) MR images, but is markedly hypointense on T_2 -weighted (T_2W) images. When the hematoma is approximately 5 days old, it appears relatively hyperintense on PW and T_1W images but is hypointense on T_2W images. At this stage, hematoma may be confused with an ocular melanoma.^{6,8,9} The hematoma usually continues to increase in signal intensity on T_1W , PW, and T_2W images and usually becomes markedly hyperintense by day 14 on all MR pulse sequences.

1.6 Retinoblastoma

Retinoblastoma, the most common intraocular tumor of childhood, is a highly malignant retinal tumor. The tumor arises from neuroectodermal cells (nuclear layer of the retina) destined to become retinal photoreceptors.^{2,10} Leukokoria, a pink-white or yellow-white pupillary reflex (cat's eye), is the most common presenting sign of retinoblastoma. Computerized tomography is most sensitive in demonstrating the presence of the typical deoxyribonucleic acid (DNA)-calcium complexes within the tumor.^{2,10} Magnetic resonance imaging is not as specific as CT scanning in the diagnosis of retinoblastoma due to its lack of sensitivity in detecting calcification. However, it is more specific than CT in differentiating retinoblastoma from other lesions that simulate retinoblastoma clinically, such as persistent hyperplastic primary vitreous (PHPV), Coats' disease, retinopathy of prematurity (ROP), toxocariasis, retinal detachment, and other so-called pseudogliomas and leukokorias.^{2,10,12,13} Lesions less than 2–3 mm in thickness are not recognized as discrete areas by MR technology to date. At times lesions less than 3 mm thick may be better visualized on post Gd-DTPA contrast MR scans due to increased contrast resolution. On MRI, retinoblastomas appear slight to moderately hyperintense to vitreous on T_1W and slightly or moderately hypointense to vitreous on T_2W MR scans. Even extensive calcification noted on CT scans may be missed in all MR pulse sequences. Retinoblastomas demonstrate moderate to marked contrast enhancement following i.v. administration of Gd-DTPA contrast material. Involvement of the Tenon's capsule, optic nerve and retrobulbar space is best evaluated on post Gd-DTPA fat-suppression T_1W MR images. MRI including Gd-DTPA contrast study appears to be the study of choice for the evaluation of intracranial spread of retinoblastoma and the association of bilateral retinoblastoma, suprasellar and pineal primitive neuroectodermal tumors (tetra lateral retinoblastoma).¹⁴

1.7 Persistent Hyperplastic Primary Vitreous (PHPV)

Persistent hyperplastic primary vitreous is caused by failure of the embryonic hyaloid vascular system to regress normally. The ocular malformation can reflect either an isolated congeni-

tal defect or may be a manifestation of more extensive ocular or systemic involvement.^{2,15,16} The MRI findings of PHPV include: (1) microphthalmos, (2) lack of calcification, (3) posterior hyaloid or retinal detachment, (4) tubular, cylindrical or other discrete intravitreal images suggestive of persistence of fetal tissue, (5) fluid level within the globe, reflecting the presence of serosanguinous fluid in either the subhyaloid or subretinal space, (6) enhancement of abnormal intravitreal tissue following i.v. administration of Gd-DTPA contrast material, (7) altered signal of lens of the involved eye compared with the other normal eye.

1.8 Coats' Disease

Coats' disease is a primary vascular anomaly of the retina, characterized by idiopathic retinal telangiectasia and exudative retinal detachment (exudative retinopathy). It is almost always unilateral and generally affects boys of 4 to 6 years of age, although it may be seen in younger children. In the early stage of the disease, MRI may yield little information. In the later stages, the exudative retinal detachment is seen as hyperintense images on all MRI pulse sequences. At times, due to lipoproteinaceous exudate, typically seen in Coats' disease, the subretinal exudate may be less hyperintense than the vitreous body on T_2W MR scans. The leaves of the detached retina in Coats' disease may be very thickened and may show moderate to significant enhancement following i.v. administration of Gd-DTPA contrast material.

1.9 Retinopathy of Prematurity (ROP)

Retinopathy of prematurity, formerly termed retrolental fibroplasia, is believed to be related to a combination of developmental (prematurity) and environmental (supplemental oxygen therapy) factors that prevent normal retinal vasculogenesis. The MRI findings of the early stage of ROP are nonspecific. The eyes may be microphthalmic. In the more advanced stages the differential diagnoses include PHPV, retinoblastoma, endophthalmitis as well as a number of pathologic conditions in which retinal detachment is a common feature.^{2,17} Retinoblastoma has rarely been reported in microphthalmic eyes with or without ROP or PHPV.

1.10 Ocular Toxocariasis

Toxocariasis results from ingestion of eggs of the nematode, *Toxocara canis*. The death of the larva results in a wide spectrum of intraocular inflammatory reactions. MRI is superior to CT for the evaluation of ocular toxocariasis. The MR findings of ocular toxocariasis consist of localized or diffuse intravitreal mass with moderate to marked contrast enhancement. The subretinal exudate has variable hyperintense signal on T_1W , PW, and T_2W MR scans.¹⁷

1.11 Malignant Uveal Melanoma

Malignant uveal melanoma is the most common intraocular tumor in adults. They are uncommon in blacks, the white:black ratio being about 15:1.⁶ Metastasis primarily involves the liver. Uveal melanomas and other intraocular lesions more than 3

mm in thickness are usually well visualized on MR scans.^{6,17} Smaller lesions are better studied with ultrasonography. The MR characteristics of melanotic lesions are thought to be related to the paramagnetic proton relaxation by stable radicals in melanin.¹⁸ The stable radicals cause a proton relaxation enhancement that shortens both T_1 and T_2 relaxation times.¹¹ Hence, uveal melanomas appear as areas of moderately to markedly high signal (greater signal intensity than vitreous) on T_1W and PW MR images. On T_2W images, melanomas appear as areas of moderately to markedly low signal (lesser signal intensity than vitreous). These MR characteristics are similar to those of retinoblastoma. Some of the melanomas may not be hypointense on T_2W images. Melanomas demonstrate moderate enhancement following i.v. administration of Gd-DTPA contrast media (Figure 2). Exudative retinal detachment, associated with choroidal melanoma is seen on MRI as dependent areas of moderate to high intensity on T_1W , PW and T_2W images. Organized exudative chronic retinal detachment and hemorrhagic subretinal fluids may simulate melanoma on MRI scans. Invasion of the sclera, extension of tumor into the Tenon's capsule or optic disk and extraocular invasion can be best detected by MR scans, particularly on post Gd-DTPA fat-suppression T_1W MR images.

1.12 Choroidal Hemangioma

Choroidal hemangiomas are congenital vascular hamartomas. Two different forms have been described: a circumscribed or solitary type and a diffuse angiomas.¹⁹ Diffuse choroidal hemangiomas are usually seen in association with Sturge-Weber disease. Choroidal hemangiomas can be diagnosed by ophthalmoscopy, fluorescein angiography, ultrasonography or CT. However, misdiagnoses are not uncommon, particularly when the angiomas are concealed by a detachment of the retina.² On MRI, choroidal hemangiomas appear hypointense to slightly hyperintense to vitreous on T_1W images and hyperintense on T_2W images. They show intense enhancement on post Gd-DTPA T_1W MR scans. MRI scans are, therefore, extremely

Figure 2 Malignant choroidal melanoma. Axial T_1W postcontrast MR image. A hyperintense enhancing mass (solid arrows) is demonstrated. The melanoma has caused retinal detachment (hollow arrow). The tumor can be easily differentiated from subretinal exudate

useful in differentiating choroidal hemangiomas from choroidal melanomas.

1.13 Uveal Metastases

A most common source of secondary carcinoma within the eye is from breast or lung. Metastatic lesions of the uvea extend chiefly in the plane of the choroid, causing relatively little increase in its thickness. Unlike uveal melanomas, which tend to form a protuberant mass, uveal metastases usually have a mottled appearance and a diffuse outline on MRI scans. Most uveal metastases appear as areas of low signal on T_1W MR scans. On T_2W images, metastases appear as areas of high signal intensity. A mucin-producing metastatic lesion (adenocarcinoma) may simulate a uveal melanoma because the proteinaceous fluid tends to decrease T_1 and T_2 relaxation times.² Uveal metastatic carcinoid lesions may simulate uveal melanomas on MRI scans.²⁰ Uveal metastases demonstrate moderate to marked enhancement following i.v. administration of Gd-DTPA contrast material. Exudative retinal detachment associated with uveal metastases can be best differentiated from metastasis on postcontrast T_1W images.

1.13.1 Choroidal Hemorrhage and Detachment

Choroidal hemorrhage and detachment may be easily mistaken for choroidal tumors.^{2,8,9} MRI is invaluable in differentiating choroidal detachments from uveal melanomas.⁸

1.13.2 Other Uveal Tumors

Neurofibroma and schwannoma of the choroid and ciliary body, adenoma, leiomyoma, and lymphoreticular proliferative disorders of the uveal tract are rare lesions involving the choroid and ciliary body which can cause diagnostic confusion with uveal melanoma. If these lesions are large enough (3 mm or more) they can be detected by MRI.¹⁰

2 MRI OF THE ORBIT

2.1 Introduction

The orbits are two recesses that contain the globes, the extrinsic ocular muscles, the blood vessels, lymphatic, nerves (II, III, IV, and V), adipose and connective tissues, and most of the lacrimal apparatus.¹ The orbit is bounded by the periorbitum (periorbital) and separated from the globe by Tenon's capsule. Anteriorly are the orbital septum and the lids. The orbital cavity is pyramidal; its apex is directed posteriorly and medially and its base is directed anteriorly and laterally as the orbital opening. Its bony walls separate it from the anterior cranial fossa superiorly, the ethmoid and sphenoid sinuses and nasal cavity medially, the maxillary sinuses inferiorly, and the lateral surface of the face and temporal fossa laterally and posteriorly. At the apex of the orbit, the optic canal and the superior and inferior orbital fissures allow various structures to enter and leave the orbit.^{1,21}

2.2 Anatomy of the Orbit

2.2.1 Orbital Septum and Eyelids

The orbital septum is a weak, membranous sheet that forms the fibrous layer of the eyelids and is attached to the margins of the bony orbit where it is continuous with the periorbital. Each eyelid or palpebra from without inwards consists of skin, subcutaneous areolar tissue, fibers of the orbicularis oculi, tarsus, and orbital septum.

2.2.2 Orbital Fatty Reticulum, Extraocular Muscles, and Optic Nerve

Within the orbit all structures are embedded in a fatty reticulum. The fibroelastic tissue that makes up the reticulum divides the fat into lobes and lobules.²¹ The six striated extraocular muscles, including the four recti and the two oblique muscles, control eye movement. The rectus muscles arise from the annulus of Zinn, which is a tunnel-shaped tendinous ring that encloses the optic foramen and the medial end of the superior orbital fissure.²²

The optic nerve is a nerve fiber tract that conveys visual sensation. It traverses the optic canal with the ophthalmic artery. The optic nerve is covered by three layers, the pia mater, the arachnoid, and the dura, all of which sheathe the nerve.

2.2.3 Lacrimal Apparatus

The lacrimal gland lies in the superolateral angle of the orbit in the lacrimal fossa. Tears produced by the gland are drained into the lacrimal sac. The lacrimal sac lies in the lacrimal groove, located in the anterior-inferomedial angle of the orbit. From the sac, the tears drain through the nasolacrimal duct into the inferior meatus of the corresponding nasal cavity.

2.3 MRI Techniques

Excellent natural contrast between various orbital tissues (water, fat, muscles, and nerves) makes the orbit an ideal organ to study by MRI. The three-dimensional capability of MRI along with its superior contrast resolution is of great assistance in localizing orbital pathology. Using a head coil, a routine MRI of the orbit usually includes a single echo short TR , short TE (TR/TE , 500–800/20–25 ms), SE sagittal view, an axial SE double echo (TR/TE , 2000–2500/20–25, 70–100 ms) and a single echo, short TR , short TE , SE axial or coronal view. Following the intravenous i.v. administration of Gd-DTPA, single echo, short TR , short TE images are obtained with or without fat-suppression techniques. Images obtained with a surface coil provide better spatial resolution; however, the apical lesions and intracranial extension of the orbital lesions may not be fully evaluated because of signal dropout, proportional to the distance from the surface coil. We use the surface coil for those lesions situated in the anterior orbit. In general, the orbital MRI study and the use of paramagnetic contrast material should be tailored according to the suspected problem of individual patients.²²

Figure 3 Normal orbital anatomy. Coronal 3 mm thick MR scan, demonstrating various anatomical structures of the orbits, nasal and paranasal sinuses. E = ethmoidal sinus, IR = inferior rectus muscle, IT = inferior turbinate, LPS = levator palpebra superioris, LR = lateral rectus muscle, MA = maxillary antrum, MR = medial rectus muscle, MT = middle turbinate, OA = ophthalmic artery, ON = optic nerve, so = superior oblique muscle, Sov = superior ophthalmic vein, SR = superior rectus muscle

2.4 MRI Anatomy of the Orbit

MRI provides the best cross sectional imaging anatomy of the orbit. The SE, short *TR* and short *TE* pulse sequences provide the most spatial resolution with exquisite anatomical details.²² The extraocular muscles, the intermuscular septae, the optic nerve, superior ophthalmic vein, ophthalmic artery, the lacrimal gland, lacrimal sac, and nasolacrimal duct are very well visualized on routine MR images (Figure 3). Smaller structures such as divisions of the ophthalmic and third cranial nerves, lacrimal vein and artery, and even ciliary vessels can be visualized on high resolution MR images, obtained with a surface coil. The orbital septum, structures of the eyelids including tarsal plates, the annulus of Zinn, and most of the tendinous portion of the extraocular muscles can be best visualized on images obtained with a surface coil.²²

2.5 MRI of Orbital Pathology

2.5.1 Developmental Orbital Cysts

MRI is particularly helpful in the evaluation of congenital anomalies of the orbit and optic system. The most frequent developmental cysts involving the orbit and periorbital structures are epidermoid and dermoid cysts and teratomas. Epidermoid and dermoid cysts appear hypointense to brain on *T*₁W and hyperintense on *T*₂W MR images. Portions of the dermoids which contain fatty tissue appear hyperintense on *T*₁W and hypointense on *T*₂W images. Epidermoid and dermoid cysts do not show enhancement with Gd-DTPA.

2.5.2 Inflammatory Conditions

Preseptal and postseptal orbital inflammation, subperiosteal phlegmon and abscess, ophthalmic vein and cavernous sinus thrombosis can be demonstrated by MRI. The main contribution of MRI to the diagnosis of sinonaso-orbital infections is

its clear demonstration of the relationship between nasal, sinus, orbital and cranial disease.²²

2.5.3 Idiopathic Orbital Inflammations (Pseudotumors)

Pseudotumors are defined as nonspecific, idiopathic, orbital inflammatory conditions for which no local identifiable cause or systemic disease can be found.²²⁻²⁴ Classically the rapid development of unilateral, painful ophthalmoplegia, proptosis and chemosis, with a rapid and lasting response to steroid therapy in an otherwise healthy patient, is highly suggestive of the diagnosis of pseudotumor. On MRI, pseudotumors usually appear as an infiltrative process which is isointense or hypointense to muscles on *T*₁W and hyperintense on *T*₂W images. On MRI, the enhancement of pseudotumors with Gd-DTPA is best demonstrated on fat-suppressed *T*₁W images. There are no specific imaging characteristics or clinical signs to establish the diagnosis of pseudotumor with absolute certainty. Idiopathic orbital myositis may simulate thyroid myopathy. However, typically, enlargement of the muscles in thyroid myopathy involves the muscle belly, sparing its tendinous portion.

2.6 Orbital Tumors

2.6.1 Lymphoma

Lymphomas, the most common malignant orbital tumors in adults, are solid tumors of the immune system. Most are composed of monoclonal B cells. The most common cytologic forms of malignant lymphoma involving the orbit are histiocytic and lymphocytic in various degrees of differentiation. True lymphoid tissue in the eye is found in the subconjunctival and lacrimal gland. This explains why most orbital lymphomas are commonly seen in the anterior portion of the orbit. The MRI findings of orbital lymphomas are usually nonspecific and at times are impossible to differentiate from those of orbital pseudotumors. Both pseudotumors and lymphomas may have an intermediate or hypointense signal in *T*₁W images (Figure 4) and appear isointense or hyperintense and even hypointense (although less common) to fat in *T*₂W images (Figure 4). Both pseudotumors and lymphomas demonstrate moderate contrast enhancement on postcontrast MRI scans.

2.6.2 Rhabdomyosarcoma

Rhabdomyosarcoma is the most common malignant mesenchymal tumor of childhood, as well as the most common primary malignant tumor of the orbit in children.^{22,25} The tumor is notorious for producing a rapidly developing unilateral proptosis. Any rapidly developing proptosis in childhood must presumptively be diagnosed as rhabdomyosarcoma. The differential diagnosis also includes leukemia and metastatic deposits (neuroblastoma), Langerhans histiocytosis, ruptured dermoid cyst, hemorrhage in a pre-existing lymphangioma, subperiosteal infection and hematoma after trauma. Rhabdomyosarcomas are both aggressive bone-destroying lesions and bone-pushing lesions. Rhabdomyosarcoma appears hypointense to brain on *T*₁W and isointense to slightly hyperintense to brain on *T*₂W images. The use of paramagnetic contrast media results in moderate to marked enhancement.²⁵ Magnetic resonance imaging is the most sensitive imaging study to differentiate rhabdomyosarcoma from most simulating lesions.^{22,25}

Figure 4 Small cell lymphoma of the orbit. Coronal T_1W (top) and axial T_2W (bottom) MR scans demonstrating normal right lacrimal gland (LG) and abnormal left lacrimal gland (hollow arrows) due to involvement by lymphoma. Notice lymphomatous involvement of left superior rectus muscle (SR) as well as extraconal fat (curved arrow)

2.6.3 Hemangiomas and Lymphangiomas

Capillary hemangiomas are the most common orbital vascular tumors that occur in infants during the first year of life. The tumor often increases in size for 6 to 10 months and then gradually involutes. On MRI, capillary hemangiomas have long T_1 and long T_2 characteristics. At times, prominent vessels can be identified within the lesion. They demonstrate marked contrast enhancement. On MR angiography, the vascular blush may not be appreciated.

Cavernous hemangiomas, the most common orbital vascular tumor in adults, appear as well-defined masses, frequently occurring within the intraconal space. On MRI, they appear as well-defined, sharply marginated, homogeneous, rounded, ovoid, or lobulated masses, which appear hypointense to brain on T_1W and hyperintense on T_2W images. They demonstrate moderate to marked contrast enhancement on MRI. The MRI characteristics of orbital schwannomas and hemangiopericytomas may be similar to cavernous hemangiomas.^{22,26}

Orbital lymphangiomas occur in children and young adults. Lymphangiomas may have distinct borders but are typically diffuse and not well capsulated. Spontaneous hemorrhage within the lesion is common.^{22,26} On MRI scans lymphangiomas are seen as homogeneous or heterogeneous, and hypointense to relatively hyperintense on T_1W and, usually, heterogeneously very hyperintense on T_2W scans. Their MRI characteristics usually help to differentiate them from hemangiomas, pseudotumors, rhabdomyosarcoma and many other lesions.^{22,26}

2.6.4 Optic Nerve Sheath Meningioma

Optic nerve sheath meningioma (ONSM) arises from the meningoendothelial cells of the arachnoid that are situated along the optic nerve sheath. Meningiomas are usually seen in

middle-aged and elderly women. ONSM presents as very slowly progressive axial proptosis and loss of vision. On MRI scans, ONSM can be seen as localized or fusiform enlargement of the optic nerve. ONSM frequently appears hypointense on T_1W and hyperintense on T_2W images as compared with the brain. ONSM demonstrates moderate to marked enhancement on post Gd-DTPA MR scans.²² Postcontrast fat-suppressed T_1W MR scans are the most sensitive images to detect ONSM. Involvement of the optic nerve by sarcoidosis may result in focal or diffuse enlargement of the optic nerve, mimicking an optic nerve meningioma on all MR pulse sequences.

2.6.5 Optic Nerve Glioma

Optic nerve glioma is a tumor arising from the neuroglia (glial cells) of the optic nerve. It is usually a tumor of childhood (2 to 8 years of age). In general, optic nerve glioma in children is considered a benign, well-differentiated, slowly growing, and noninvasive astrocytoma (pilocystic astrocytoma). However, optic nerve glioma in adults is a rare but invasive malignant astrocytoma (usually glioblastoma multiformis). Bilateral optic nerve gliomas are characteristic of neurofibromatosis type 1 (NF1). Optic nerve gliomas are seen on MRI as a well-defined, fusiform enlargement of the optic nerve. Diffuse, tortuous enlargement of the optic nerve with a characteristic kinking and buckling appearance is a characteristic feature of the childhood form of optic glioma. On T_1W MR scans, gliomas appear isointense or slightly hyperintense compared with the white matter. On T_2W images they appear hyperintense compared with the white matter.²² The use of paramagnetic contrast media results in moderate to marked enhancement. MRI remains the study of choice for the evaluation of optic gliomas. Intracranial extension of optic nerve gliomas and associated intracranial pathological changes in patients with neurofibromatosis can be best appreciated on MRI scans.²²

2.7 Optic Neuritis

Optic neuritis is an acute inflammatory process involving the optic nerve. The process may be idiopathic, immune-mediated, metabolic, and infective in nature.^{27,28} Multiple sclerosis is the most common cause of optic neuritis;^{28,29} visual loss is typically unilateral in patients with demyelinating optic neuritis. A recent study by Beck et al.²⁹ has shown that intravenous methylprednisolone followed by oral prednisone will speed the recovery of visual loss due to optic neuritis. On MR, the optic nerve in patients with optic neuritis may infrequently appear diffusely enlarged. On T_2W MR scans, the involved optic nerve may be slightly or moderately more hyperintense than the one on the normal side. Most patients with acute idiopathic optic neuritis and with no other neurologic disorder have the same areas of high-intensity signal in the cerebral white matter on T_2W MR scans that are found in patients with multiple sclerosis. In patients with optic neuritis, contrast enhancement on MRI is often subtle or present in a short segment of the optic nerve. It is best demonstrated by comparing pre- and post-contrast T_1W MR images or on postcontrast fat-suppressed T_1W MR scans.²²

2.8 Lacrimal Gland Tumors

Epithelial tumors represent approximately 50% of masses involving the lacrimal gland. Half of these are pleomorphic (benign mixed) adenomas; the other half are malignant.³⁰ Of the malignant tumors, adenoid cystic (adenocystic) are the most common.³¹ The nonepithelial masses of lacrimal gland fossa include lymphoid-inflammatory lesions, that is, benign dacryoadenitis, pseudotumor, and malignant lymphoma.³¹ MRI is the study of choice for the evaluation of lacrimal gland tumors. Benign, mixed tumors appear as well-defined encapsulated masses and have long T_1 and long T_2 MR signal characteristics. The tumor may be homogeneous or heterogeneous. The use of paramagnetic contrast material results in moderate to marked enhancement. The heterogeneity within the tumor may be better appreciated on T_2W and postcontrast T_1W MR images. Malignant lacrimal gland tumors may show poor margins and an infiltrative character. Invasion of the surrounding tissues and intracranial extension can be best evaluated on MRI scans.^{22,31}

3 MRI OF THE EAR

3.1 Introduction: Anatomy of the Ear

The ear is essentially a distance receptor concerned with the collection, conduction, modification, amplification and parametric analysis of the complex soundwaves which impinge on the head. The ear is subdivided into three major areas: the outer ear, the middle ear, and the inner ear. Each region has a specific function. The outer ear channels sound to the tympanic membrane (ear drum). The middle ear is an air-filled space (tympanic cavity), connected via the eustachian tube to the nasopharynx. Lying across the tympanic cavity are three small bones; the malleus, the incus and the stapes. The stapes footplate touches a membrane called the oval window, located between the middle ear and the inner ear.³² A second membrane-covered opening called the round window is located in the cochlea below the oval window. This connects the inner ear with the middle ear and maintains a constant (perilymphatic fluid) pressure within the cochlea. The essential function of the tympanic cavity and its ossicles is the efficient transfer of energy from the air to the perilymphatic fluids which surround the cochlea.³² The inner ear contains sensory receptors for hearing and balance. It consists of three main parts: the cochlea, the vestibule, and the semicircular canals. The inner ear is composed of the membranous labyrinth and the osseous labyrinth. The membranous labyrinth has two major subdivisions, a sensory portion called the sensory labyrinth and a nonsensory portion designated as the nonsensory labyrinth. The sensory labyrinth lies within the petrous portion of the temporal bone. It contains two intercommunicating portions: (1) the cochlear labyrinth that consists of the cochlea and is concerned with hearing, and (2) the vestibular labyrinth that contains the three semicircular canals, the saccule and utricle, (two small sacs), occupying the vestibule, all of which are concerned with equilibrium. These hollow chambers are filled with fluid, known as endolymph, that resembles intracellular fluid. The nonsensory element of the membranous labyrinth is formed by the endolymphatic duct and sac, whose main func-

tion is believed to be the degradation and absorption of the endolymph, produced in the sensory labyrinth, i.e. the cochlea and vestibule. All of the structures of the membranous labyrinth are enclosed within hollowed-out bony cavities that are considerably larger than their membranous contents. These bony cavities assume the same shape as the membranous chambers and are referred to as the osseous labyrinth. The bony cavities of the osseous labyrinth contain fluid, known as perilymph, that bathes the external surface of the membranous labyrinth.

The sound vibrations travel through the middle ear and then through the ossicular chain to the oval window. This in turn sets the perilymph in the cochlear labyrinth in motion. Stimulated by the fluid motion, sensory receptors (hair cells) in the cochlea generate nerve impulses that are transmitted by the cochlear nerve and auditory pathway to the auditory center in the temporal lobe of the brain. Impulses generated in the sensory cells of the semicircular canals and vestibule are carried to the brain by the vestibular nerve.

The essential function of the vestibular labyrinth is to provide the central nervous system (CNS) with a constant flow of information concerning the static position of the head in space, or its state of linear or angular acceleration or deceleration.^{32,33}

3.2 Acoustic and Facial Nerves

Acoustic nerve consists of the cochlear nerve and the vestibular nerves (superior and inferior). These are joined into a common trunk that enters the internal auditory canal with the facial nerve. The facial nerve then travels within the temporal bone for some 33 mm through a tortuous bony canal, known as the fallopian canal, before it enters the parotid gland.

3.3 MRI Anatomy of the Ear

MRI remains the study of choice for imaging evaluation of the membranous labyrinth, and the vestibulo-cochlear and facial nerves. The osseous labyrinth, cortical bones, and the air filled mastoid cells appear hypointense in all pulse sequences. The endolymphatic and perilymphatic fluid within and surrounding the membranous labyrinth provides MR signal, resulting in visualization of the membranous labyrinth on various MR pulse sequences (Figure 5). MRI remains the study of choice for the evaluation of the membranous labyrinth, and the vestibulo-cochlear and facial nerves. Cochlear and vestibular divisions of the acoustic nerve and the entire course of facial nerve including its parotid segment can be visualized with exquisite details on MR scans.

3.4 Pathology using MRI of the Ear

The main contribution of MRI to the diagnosis of ear disorders is its clear demonstration of the membranous labyrinth, cochlear, vestibular, and facial nerves. The use of paramagnetic contrast material enhances the sensitivity and at times specificity of MRI in the evaluation of certain pathological conditions. Gd-DTPA contrast has been shown to play an important role in the detection of inflammatory (Figure 6), autoimmune, and neoplastic diseases of the membranous labyrinth as well as soft tissue tumors and inflammatory and infiltrative processes of the ear.^{34,35}

Figure 5 Normal anatomy of the ear: 3 mm axial proton-weighted (top) and T_2W (bottom) MR scans. The cochlea (c), vestibule (V), lateral semicircular canal (L), posterior semicircular canal (P), endolymphatic sac (ES), cochlear nerve (CN) and inferior vestibular nerve (vn) are shown

3.5 Developmental Anomalies of the Ear

Computerized tomography scanning remains the study of choice for the evaluation of ear anomalies. MRI provides little information in the evaluation of patients with anomalies of the external and middle ears. In these patients MRI may be used to evaluate the facial nerve. Inner ear anomalies such as Mondini anomaly, large vestibular aqueduct, and Michel anomaly are best evaluated on CT scans. In Mondini anomaly, MRI reveals fluid-filled cystic dilatation of the membranous labyrinth. In patients with large vestibular aqueduct, MRI reveals fluid-filled cystic dilatation of the endolymphatic duct and sac.³³

3.6 Inflammatory Conditions of the Ear

CT remains the study of choice for the evaluation of acute and chronic otomastoiditis and their complications, including acquired cholesteatomas.³⁴ The main contribution of MRI to the evaluation of the inflammatory conditions of the ear is its clear demonstration of the involvement of membranous labyrinth and associated intracranial complications (Figure 6). T_1 -weighted MRI sequences obtained following the use of paramagnetic contrast material are most informative, as they readily demonstrate abnormal intralabyrinthine enhancement (Figure 6). In patients with vestibulocochlear or facial neuronitis, MRI may demonstrate moderate to marked contrast enhancement of the involved nerve (Figure 7).

3.7 Cholesteatomas and Cholesterol Granulomas

Cholesteatomas of the ear may be congenital or acquired. Histologically the pathology of congenital cholesteatomas is similar to that of the acquired varieties, namely, a cavity, lined with keratinizing stratified squamous epithelium which encapsulates desquamated epithelial cells, keratomatous materials, and minimal cholesterol.

Cholesterol granulomas of the ear are believed to be a tissue response to hemorrhage and an irritant foreign body, i.e. cho-

Figure 6 Acute otomastoiditis and labyrinthitis: 3 mm axial post-Gd-DTPA T_1W MR scans. There is marked enhancement of granulation tissues within the mastoid air cells (M). Notice marked enhancement of left membranous cochlea (white, short and long arrows). There is slight enhancement of the right cochlea (black arrow); patient had bilateral acute otomastoiditis, left more so than right

lesterol crystals and other blood byproducts. Cholesteatomas and cholesterol granulomas of the petrous apex are the most common expansile, slowly destructive, lesions of the petrous bone.³⁴ On CT scans they are very difficult to differentiate from each other. However, on MRI, cholesteatomas have a long T_1 and long T_2 characteristics, whereas, cholesterol granulomas have a short T_1 and long T_2 characteristic. Both lesions if not infected demonstrate no contrast enhancement. CT scanning is superior to MRI for the detection of middle ear cholesteatomas.³⁴ MRI however, is superior to CT scanning for the evaluation of infected cholesteatomas, petrous apex and intradural cerebellopontine (CPA) cholesteatomas (epidermoids), as well as for the evaluation of cholesteatomatous involvement of the facial nerve, membranous labyrinth, and intracranial structures.

Figure 7 Ramsey hunt syndrome: 3 mm axial post-Gd-DTPA T_1W MR scan. There is marked enhancement of the meatal segment (arrow head) and tympanic segment (solid arrows) of the facial nerve. Note enhancement of the superior vestibular nerve (hollow arrow)

3.8 Tumors of the Ear

The diagnostic approach to evaluating a patient suspected of having a lesion of acoustic and facial nerves or a CPA tumor has changed as the resolution of MRI has improved and as the sensitivity and specificity of MRI has been established. MRI remains the initial imaging study of choice for the evaluation of acoustic and facial neuromas, and most CPA tumors. The most common tumors of the temporal bone are Schwann-cell tumors that arise from the vestibular divisions of the acoustic nerve; as such, they are actually vestibular schwannomas. Bilateral vestibular schwannomas are characteristic of neurofibromatosis type 2 (NF2).

Vestibular schwannomas are the most common CPA masses.³⁶ Meningiomas are the second and epidermoid cysts are the third most common CPA masses. Magnetic resonance imaging is the most useful diagnostic test to diagnose as well as to differentiate these CPA masses.³⁷ The use of paramagnetic contrast material significantly increases the sensitivity of MRI. Tumors as small as 2 mm in size can be detected along the course of facial and acoustic nerves. The use of paramagnetic contrast has allowed for the first time the detection of tiny intralabyrinthine schwannomas,³⁸ and inflammatory processes of the facial nerve which were extremely difficult to diagnose even with high-resolution CT scan.^{39–41} Parangliomas or chemodectomas (glomus tumors) are the second most common tumors of the temporal bone.⁴² Parangliomas appear as regions of hypointensity on T_1W and hyperintensity on T_2W MR scans.⁴² There are frequently areas of signal void related to rapid arterial flow present in the matrix of these hypervascular tumors. Parangliomas demonstrate significant enhancement following intravenous (i.v.) administration of paramagnetic contrast material.⁴² Other benign and malignant tumors that involve the ear, including adenoma, carcinomas, adenocarcinomas, papillary adenocarcinomas, adenoid cystic carcinomas, rhabdomyosarcomas, chondrosarcomas, osteosarcomas, osteoclastomas, chordomas, and other mesenchymal tumors can be adequately evaluated by MRI.

4 MRI OF THE NASAL CAVITY AND PARANASAL SINUSES

4.1 Introduction

The nasal cavity, the first of the respiratory passages, extends from the roof of the mouth upwards to the base of the skull. It is divided by the nasal septum into two halves which open on the face through the nostrils, and communicates behind with the nasopharynx.⁴³ The lateral wall of the nasal cavity is irregular, owing to the presence of three bony projections, the inferior, middle, and superior nasal conchae (turbinates). The conchae project downward and slightly medially and divide the passageway into meatuses, or channels of air. The inferior meatus receives the orifice of the nasolacrimal duct. The middle meatus receives the opening of the ipsilateral anterior ethmoidal air cells, frontonasal duct of the frontal sinus and the ostium of the maxillary sinus. The superior meatus receives the opening of the ipsilateral posterior ethmoidal air cells. A narrow interval, the spheno-ethmoidal recess, separates

the superior turbinate from the anterior surface of the body of the sphenoid, through which each sphenoidal sinus opens into the nasal cavity.⁴³ The nasal mucous membrane lines the nasal cavity. It is continuous with the mucous membrane of the nasopharynx and paranasal sinuses.

The paranasal sinuses are air-filled cavities and include the frontal, ethmoidal, sphenoidal and maxillary sinuses. They are lined with upper respiratory mucosa, continuous with that of the nasal cavity.⁴³ The frontal sinuses are rudimentary or absent at birth, they are usually fairly well developed by the seventh or eighth years, and they reach their full size after puberty. The ethmoidal sinuses are small, but of clinical importance, at birth; they grow rapidly between the sixth and eighth years and after puberty.⁴³ The sphenoidal sinuses are present at birth, as minute cavities within the body of the sphenoid bone, but their main development takes place between the third and tenth years and after puberty. The maxillary sinuses are present as minute cavities at birth, but do not, however, reach full size until after the eruption of all the permanent teeth. The natural opening of the maxillary sinus is high above its floor and communicates with the lower part of the hiatus semilunaris to be drained into the middle meatus.

4.2 MRI Anatomy of Nasal and Paranasal Sinuses

The nasal cavity and paranasal sinuses can be visualized by MRI, using head coil or surface coil. Images obtained with head coil are preferred because of the size and deep location of posterior sinonasal cavities. The cortical bone and air of the sinonasal structures do not provide MR signal, and therefore they appear hypointense in all pulse sequences. The mucosa of nasal structures, however, appear as intermediate signal on T_1W and increased signal (hyperintense) on T_2W images. The normal mucosa of the paranasal sinuses are very thin and cannot be visualized on MR scans.

4.3 MRI of Sinonasal Pathology

4.3.1 Congenital Anomalies

Magnetic resonance imaging remains the study of choice for the evaluation of congenital sinonasal anomalies such as sphenoidal, sphenoethmoidal, ethmoidal, frontonasal, and intraorbital encephaloceles. Magnetic resonance imaging is very useful for the evaluation of intranasal–extranasal dermoids and nasal gliomas.

4.3.2 Inflammatory Conditions

Standard sinus roentgenograms, CT and, more recently, MRI are currently the most used imaging methods to assess paranasal pathology.⁴⁴ Computerized tomography remains the imaging study of choice for appropriate evaluation of patients with acute sinusitis associated with complications such as subperiosteal or orbital abscesses and for patients with chronic sinusitis.^{44,45} Magnetic resonance imaging is also very sensitive in the evaluation of acute sinonasal pathology. The main contribution of MRI to the diagnosis of sinonasal–orbital infections is its clear demonstration of the relationship between nasal, sinus, orbital and cranial diseases. Orbital cellulitis, subperiosteal phlegmon and abscess can be readily visualized on MR scans. Magnetic resonance imaging is superior to CT in

demonstrating sinogenic complications such as thrombosis of the superior ophthalmic vein, thrombosis of the cavernous sinus, and intracranial complications such as epidural abscess, focal or diffuse encephalitis and brain abscesses.

4.3.3 Tumors

Magnetic resonance imaging provides excellent delineation of tumor from surrounding soft tissue, inflammatory tissue, and retained secretions within the sinuses.^{46–52} It might be anticipated that the typical appearance of edema or retained secretions within the sinuses on MR images would be of low intensity on T_1W and high intensity on T_2W images, reflecting the high water content associated with the excessive interstitial fluid or retained secretions. However, because of the frequent chronic nature of these benign processes in patients who have a nasal cavity or paranasal sinus tumor, especially in those patients in whom an advanced tumor has been diagnosed, sufficient time has elapsed to allow for the concentration of high water affinity mucoproteins and the absorption of free water. This leads to various degrees of shortening of both T_1 and T_2 relaxation times.⁴⁵ The areas of complete desiccation appear as low signal on T_1W , PW, and T_2W MR images.

Sinonasal carcinomas are highly cellular tumors with little free water; as such, they appear as low to intermediate signal intensity on T_1 - and T_2W images (Figure 8). Inflammatory diseases have intermediate signal intensity on T_1W and high signal intensity on T_2W images [Figure 8(b)]. Benign pathological processes within the nasal cavity and paranasal sinuses, such as polyps, papillomas, low grade adenocarcinomas, (minor salivary gland tumors), and schwannomas have higher signal intensity than carcinomas on T_2W images (Figure 9). The use of paramagnetic contrast material often offers additional information.⁵² In most instances, Gd-DTPA contrast enhancement of the tumor is less than the enhancement of the normal mucosa and associated inflammatory changes. Gd-DTPA is extremely helpful in detecting intracranial extension of a sinonasal tumor.

Magnetic resonance imaging has proved valuable in the diagnosis of most other tumors of the sinonasal cavity such as rhabdomyosarcomas, lymphomas, angiomas, angiofibromas, hemangiopericytomas, chondrosarcomas, osteogenic sarcomas malignant melanomas, and metastases.⁴⁵

Figure 8 (a) Sinonasal squamous cell carcinoma. Sagittal T_1W MR image. A hypointense mass (M) is demonstrated, involving the nasal cavity and ethmoidal sinus. The tumor has caused obstruction of the ostium of the sphenoid sinus, resulting in hyperintense retained secretions within the adjacent sphenoid sinus (S). (b) Coronal T_2W MR images. A relatively hypointense mass (M) is demonstrated, compared with hyperintense retained secretions in the ethmoidal sinuses (E)

5 MRI OF THE NECK

5.1 Introduction: Anatomy of the Neck

The neck is the junctional region between the head and thorax and upper limbs. Its rostral limits are the base of the skull posteriorly and the inferior border of the mandible anteriorly. Caudally it is bounded by the thoracic inlet and pectoral girdle (clavicle, manubrium of sternum, acromion and spine of the scapula), a plane which parallels the first rib. The neck contains the cervical vertebrae and muscles, the pharynx, the larynx, cervical esophagus, cervical trachea, thyroid gland, salivary glands lymph nodes, and vessels and nerves that either supply the various organs of the neck or are in transit between the head, thorax, and upper limbs.⁵³

5.2 MRI Techniques

Our protocol for the upper neck (above the angle of the mandible) uses a head coil and a neck coil for the lower neck. The nasopharynx, parapharyngeal space, infratemporal fossa, masticatory space, oropharynx, tongue, and salivary glands are ideally suited for evaluation by head coil. The larynx is best evaluated by using a surface coil. Thyroid gland and parathyroid glands and lower neck may be evaluated by both head and surface coils. A routine MRI of the neck should include at least a sagittal T_1W localizer and axial SE double echo pulse sequences. At times, additional coronal T_1W or T_2W images may be obtained. The use of Gd-DTPA contrast material, gradient echo images, and fat-suppression pulse sequences should be tailored according to the clinical information and initial evaluation of the sagittal T_1W and axial SE double echo pulse sequences.

Figure 9 Frontal sinus polyp. Coronal T_2W MR image. A hyperintense polyp (arrows) is demonstrated within an otherwise aerated frontal sinus. The signal intensity of the polyp (benign process) is greater than that of the carcinoma (malignant process), seen in Figure 8(b)

5.3 MRI Anatomy of the Neck

Magnetic resonance imaging offers the best soft tissue contrast resolution and therefore remains the study of choice for imaging the anatomy of the soft tissue of the neck.⁵⁴ The larynx, pharynx, tongue, floor of the mouth, salivary glands, thyroid gland, parapharyngeal space, infratemporal fossa, mastoid space, and vascular structures of the neck can be visualized with exquisite anatomical detail.⁵⁴⁻⁵⁶

5.4 MRI Pathology of the Neck

5.4.1 Developmental Neck Cysts

Magnetic resonance imaging is extremely helpful in the evaluation of congenital anomalies of the neck.⁵⁵ The most frequent developmental conditions involving the neck are brachial cleft anomalies, cystic hygromas (lymphangiomas), dermoids and epidermoids, and teratomas. Most of these lesions have characteristic MRI findings that should help the radiologists make the diagnosis.⁵⁵

5.4.2 Inflammatory Conditions

The main contribution of MRI to the diagnosis of neck infections is its clear demonstration of the relationship between various potential spaces within the neck and adjacent structures

Figure 10 (a) Chronic laryngeal and perilaryngeal infection: 5 mm axial post-Gd-DTPA T_1W MR scans. A large enhancing inflammatory induration (arrows) is demonstrated, associated with marked thickening of the left aryepiglottic fold (AE), and an area of fluid loculation, proved to be pus (P), in the paralaryngeal space. Notice the normal right thyroid cartilage (arrowhead) and partial destruction on the left side. c = common carotid, E = external jugular vein, IJ = internal jugular vein, P = pus, SM = sternocleidomastoid muscle. (b) Coronal post-Gd-DTPA MR scan (4 mm). This coronal MR image demonstrates the caudal and cephalad extension of laryngeal and paralaryngeal inflammation (arrows). Notice marked thickening of the left aryepiglottic fold (AE), lateral displacement of the left internal jugular vein (IJ), and bilateral laryngoceles (L). LV = laryngeal vestibule, MA = masseter muscle, MP = medial pterygoid muscle, SG = submandibular gland, SM = sternocleidomastoid muscle, T = palatine tonsil, U = uvula

including base of the skull and intracranial structures. Soft tissue induration, edema, and fluid collections (pus) can be readily demonstrated on MRI (Figure 10). Magnetic resonance imaging is highly sensitive for the detection of early and late inflammatory changes of the bone marrow of the bony structures of the head and neck as well as the temporo-mandibular joint.

5.5 Neck Tumors

Magnetic resonance imaging is capable of depicting most benign and malignant tumors of the neck. On MRI, most tumors have long T_1 and T_2 characteristics.⁵⁴⁻⁵⁷ The T_2W images are most valuable for detecting differences in signal intensity of the pathological process.⁵⁴⁻⁶⁰ Magnetic resonance imaging remains the study of choice for imaging evaluation of nasopharyngeal, and parapharyngeal, salivary gland tumors. In most patients with laryngeal tumor, MRI appears to be more appropriate than a computerized tomography (CT) scan for evaluating the extent of laryngeal tumor.⁵⁷ Involvement of the pre-epiglottic space, paralaryngeal space, postcricoid region, as well as cartilage invasion by laryngeal tumor can be readily visualized on MR scans.⁵⁷ Magnetic resonance imaging is as sensitive as CT for demonstrating nodal (lymph) diseases of the neck.⁵⁹ Gd-DTPA contrast studies have been shown to play an important part in the detection and diagnosis of certain lesions of the neck.⁶¹

Robert Lufkin

University of California, Los Angeles, CA, USA

1 INTRODUCTION

MRI has revolutionized head and neck imaging and has replaced computerized tomography (CT) as the study of choice for many lesions of the extracranial head and neck. MRI easily surpasses CT in its ability to differentiate subtle differences in soft tissue boundaries and extensions of tumors of the head and neck. The beam hardening artifacts on CT images from dental amalgam and dense cortical bone of the mandible, skull base, shoulders, and other areas are also not a problem with MRI. Multiplanar imaging capabilities and lack of ionizing radiation make MRI the preferred imaging study for many head and neck processes.

The exceptions where CT is still indicated are many inflammatory diseases, congenital malformations of the temporal bone, fibro-osseous lesions, and fractures. In patients with a contraindication to MRI, difficult or confusing cases where the MRI findings are inconclusive, or in situations where MRI is not available, CT is often very valuable. In the paranasal sinuses and middle ear disease where lesions are often defined by their relationship to thin cortical bone and air, CT is the study of choice. However, MRI is the preferred imaging modality for the majority of neoplastic conditions in most areas of the head and neck.

Cancers in the head and neck are often more accessible by visual inspection or palpation than similar lesions in brain, lung, abdomen, and pelvis. Therefore the role of any imaging modality in the evaluation of head and neck cancer is usually to define the deep extension of tumors, rather than to detect their presence. Mucosal changes are usually best evaluated by direct inspection during physical examination. Some submucosal tumors do not show findings other than fullness or bulging on physical examination. MRI is a powerful tool for the determination of deep disease extension and the relationship of the tumor to significant structures such as major vessels and nerves, which helps define therapeutic options.

2 TECHNIQUE

Surface coils greatly increase the MRI signal-to-noise ratio and allow higher spatial resolution of most examinations of the head and neck. While acceptable studies of the sinuses and naso- and oropharynx may be obtained with the standard head coil, the use of surface coils for examination of the larynx,

hypopharynx, neck, and temporal bone is practically essential.^{1,2}

The new bilateral phased array surface coil provides high resolution with a higher signal-to-noise ratio compared with standard surface coils. Each phased array coil element has its own preamplifier, receiver channel, and digitizer, allowing the collection of data and generation of images individually and subsequent combination into a composite image. This approach is now routinely used in many centers for MRI of the temporal bone and temporomandibular joint (Figure 1).

While specialized surface rf coils are important factors that make quality magnetic resonance images of the head and neck possible, perhaps the most significant factor in the superiority of MRI over CT scanning in this area is the high soft tissue contrast resolution of MRI. Unlike the central nervous system where virtually no MRI signal from fat is present, the abundance of fat-water interfaces in the extracranial head and neck, which literally defines the anatomy of this region, greatly influences the selection of pulse sequences for optimum image contrast.

Although there is considerable variation in imaging approaches to the head and neck, a standard MRI sequence would include T_1 - and T_2 -weighted axial images, and T_1 -weighted coronal images for most lesions. T_1 -weighted sagittal images are necessary for the larynx, mastoid portion of the facial nerve, and midline lesions.

Currently, T_2 -weighted fast spin echo (FSE) imaging has replaced the regular T_2 -weighted spin echo image for most studies of the head and neck at many centers.³ In FSE acquisition, multiple refocused echoes are generated during a single TR (usually 8–16 echoes train), resulting in a short scan time and a better signal-to-noise ratio. The reduced scan time allows higher image matrix acquisition, such as 512 instead of 256, for improved spatial resolution. The drawbacks of FSE include fewer slices obtained for the same TR and less sensitivity to susceptibility effects.

Other parameters commonly used in head and neck MRI are an FOV (field of view) of 18–20 cm and slice thickness of 3–4 mm. A 192×256 matrix is routinely used in most of head and neck MRI, except for high resolution temporal bone MRI where a 384×512 matrix is used.

The role of gadolinium contrast agents in MRI examinations of the head and neck has been investigated.⁴ Although gadolinium does enhance most head and neck tumors, it may also obscure the tumor margin in some cases because of the presence of enhancement within normal tissue resulting in reduced fat/tumor contrast. Fat suppression gadolinium enhancement MRI, therefore, was introduced to improve the lesion conspicuity following contrast administration. This technique is most valuable in regions with large amounts of fat, such as the orbit. In other regions of the head and neck the advantages of this technique are less well defined.

Although gadolinium administration adds information about whether the suspected tumor does or does not enhance, the clinical relevance of this information has been questioned in some cases. When intracranial extension is present, however, gadolinium can clearly improve the detection of the blood-brain barrier and leptomeningeal pathology. For these reasons many centers now limit their use of gadolinium to studies of the orbit and other regions close to the skull base where leptomeningeal and perineural pathology is a possibility.

Figure 1 Intracanalicular acoustic neuroma. (a) Axial T_1 -weighted image without contrast barely resolves the abnormality. (b) Following contrast administration, there is dense enhancement by the tumor. (c) High resolution (512 matrix) surface coil T_2 -weighted axial image through the contralateral side shows clearcut depiction of the normal internal auditory canal contents. (d) View through the abnormal side shows the tumor without the use of a contrast agent. Some investigators are now questioning the added value of the contrast study

3 TEMPORAL BONE

MRI is the modality of choice to evaluate sensorineural hearing loss and to a large extent to evaluate the facial nerve in its course through the temporal bone. High-resolution technique is critically important in the imaging of the temporal bone.⁵ In our institution, a bilateral phased array coil is used with 3 mm interleaved slices. T_1 -weighted spin echo and T_2 -weighted FSE images as well as gadolinium enhanced T_1 -weighted images are obtained. Gadolinium may also help in the detection of small intracanalicular acoustic tumors, although the possibility of inflammatory enhancement simulating a neoplasm must always be considered.⁶

The most common CP angle tumor is the acoustic neuroma that appears as an enhancing mass often extending into the internal acoustic canal (IAC) (Figure 2). While gadolinium enhanced MRI clearly delineates the tumor extension and improves detection of the intracanalicular acoustic neuroma, recent studies using high-resolution T_2 -weighted images now question its value.⁷

Meningioma is the second most common CP angle tumor, and characteristically shows broad dural attachment. They are isointense to the cerebral cortex on T_2 -weighted images in the majority of cases. Hyperostosis and dural thickening are often associated with meningioma. Following gadolinium administration, meningioma typically shows enhancing dural extension of the tumor.

Epidermoid (primary cholesteatoma) is a congenital lesion resulting from inclusion of ectoderm during early fetal life. The epidermoid contains keratin debris and solid cholesterol. The signal intensity of the tumor depends on the proportion of these two elements. When keratin debris predominates, the tumor appears of low signal on T_1 - and of high signal on T_2 -weighted images. The cholesterol portion gives a high signal on T_1 -weighted images. The absence of gadolinium enhancement is characteristic.

CT remains the imaging study of choice at the present time for inflammatory disease and most other conditions resulting in conductive hearing loss. Important information about the status of the ossicles and bony covering of the facial nerve canal is still best obtained with CT. CT can also best visualize tumors and metabolic diseases affecting the middle ear and mastoid air cells. For the remainder of lesions of the temporal bone, CT and MRI will continue to play complementary roles in the imaging workup. Depending on the location and particular pathology, each of the imaging modalities will contribute information.

4 SALIVARY GLANDS

The preferred method of imaging the salivary glands has evolved with new developments in imaging technology as well as clinical needs. While sialography is still used to evaluate in-

Figure 2 Acoustic neuroma. This middle-aged man presented with left sided sensorineural hearing loss. (a) Axial T_1 -weighted image shows a rounded soft tissue mass (arrowed) centered over the right internal auditory canal extending to the cerebellopontine angle. (b) Axial T_2 -weighted image shows similar findings. (c) Axial T_1 -weighted image following contrast administration shows uniform enhancement

inflammatory or autoimmune diseases of the salivary glands, MRI has replaced sialo CT scanning for the imaging evaluation of the majority of masses in the major salivary glands.⁸⁻¹⁰

While 80% of major salivary gland tumors occur in the parotid gland, inflammatory lesions are the most common in the submandibular gland. The sublingual gland is the smallest major salivary gland. Tumors originating from the sublingual gland are relatively rare. Therefore, MRI is most frequently indicated for evaluation of parotid masses.

T_1 -weighted images in the axial plane provide excellent contrast among most tumors, parotid gland, and parapharyngeal fat, allowing differentiation of an intraparotid from extraparotid gland masses (Figure 3). These views are supplemented with coronal or sagittal views when there is a suggestion of temporal bone involvement. Although poor tumor margin and low signal intensity on T_2 -weighted images has been reported to predict the high grade of malignancies in parotid gland tumors to some extent this is not universally accepted, and determinations of histology by imaging studies is generally not possible. This is in part due to the unusual, and variety of, histology found in parotid tumors. Fortunately, fine needle aspiration (FNA) is a simple, lower cost and relatively non-invasive method to determine the nature of the tumor, and has been widely applied in large clinical series.

The real advantage of MRI in evaluating parotid masses is its ability to determine more accurately whether the intraparotid tumor is within the superficial or deep lobe. The superficial and deep lobes of the parotid gland are not based on an actual anatomical structure but, rather, are defined by their location relative to the main trunk of the facial nerve. Coronal images are sometimes useful to determine the distance of the parotid mass from the stylomastoid foramen, which is crucial information for a surgeon. Malignant tumors in close relation to the facial nerve may require excision of part of that structure and subsequent microsurgical repair or transposition of nerve VII. Access to larger, deeper lesions may require division and reflection of the ramus of the mandible. This valuable information is easily obtained with MRI.¹¹⁻¹³

5 PARANASAL SINUSES

As stated before, MRI is primarily indicated for sinus tumors rather than inflammatory or fibro-osseous diseases. Although cortical bone and air do not return a signal on MRI, cortical bone can often be visualized as a lower signal between the layers of high signal soft tissue and mucosa covering the sinus wall. MRI allows excellent delineation of solid tissue masses surrounded by secretions within the paranasal sinuses.^{14,15} Erosions of the bony walls can be demonstrated on MRI as the absence of signal void normally present in cortical bone (Figure 4). For extensions beyond the bony sinuses, MRI is the clear study of choice because it differentiates skeletal muscle from tumor extension. In cases where there is a question of extension to the anterior or middle cranial fossa, MRI with gadolinium enhancement remains the study of choice.

MRI is also valuable for repeated follow-up studies for diseases of children such as juvenile angiofibroma where multiple studies are required and radiation dose becomes a factor. The high soft tissue contrast capabilities of MRI in distinguishing low protein fluids, high protein fluids, soft tissues, and normal

Figure 3 MRI guided aspiration cytology of a parotid mass. Several attempts at needle biopsy in the clinic without imaging guidance were uninformative. (a) Axial T_1 -weighted image shows the superficial parotid mass (arrowed). (b) Axial T_2 -weighted image shows heterogeneous areas of high signal which are nonspecific. This may be seen with a variety of benign and malignant conditions. (c) Axial T_1 -weighted image following MRI compatible needle placement shows the linear signal defect of the needle entering the mass (arrowed). The cytology revealed adenocarcinoma

musculature make MRI ideal to differentiate sinus tumor from secondary obstructed sinuses.¹⁴

One possible pitfall encountered in MRI of inflammatory sinus disease is signal void seen in patients with desiccated lesions such as fungus infection. Unlike nonfungus sinusitis, mycetoma is of low signal intensity on both T_1 - and T_2 -weighted images, simulating well pneumatized normal sinuses. This is due to the presence of paramagnetic substances such as manganese, iron, and calcium as well as desiccated debris within mycetoma which do not contain any free water. The fungus infection can be clearly demonstrated on CT, which is another reason that the mainstay for imaging inflammatory sinus disease will continue to be CT.

6 NASOPHARYNX

The lack of motion and abundant facial planes of the nasopharynx result in high quality MRI.¹⁶ Retropharyngeal adenopathy, tumor infiltration beyond the pharyngobasilar fascia, and hypertrophic lymphoid tissue are all better identified on MRI than on CT. The main goal of MRI examination is to evaluate the extension of primary tumor as well as nodal metastases. T_1 -weighted images are usually adequate for examining the nasopharynx because of the abundance of loose areolar tissue between various muscle groups and bundles. Tumors can be identified as low signal regions on T_1 -weighted images and high signal on T_2 -weighted images in these loose areolar planes (Figure 5).

The configuration of the nasopharynx is dominated by a very tough fascial membrane called the pharyngobasilar fascia. This tough fascia represents a continuation of the pharyngeal constrictor muscles and extends from the base of the skull down to the level of the hard palate. Its function is to maintain the airway as an open channel for breathing during normal activities and during chewing. Only malignant tumors and very aggressive inflammatory processes such as mucormycosis will pass from the mucosa of the nasopharynx through the pharyngobasilar fascia to involve the structures within the parapharyngeal space. MRI can routinely show the pharyngobasilar fascia and destruction of this tough fascia which indicates the aggressive nature of mass.

The nasopharynx remains an area that is obscure to casual clinical examination due to gag reflex or poor patient cooperation. Its proximity to the skull base makes cancers in this region particularly devastating. Most malignancies of the nasopharynx are squamous cell carcinoma. The presenting symptoms of nasopharyngeal carcinoma vary widely. The most common complaints of patients presenting with nasopharyngeal tumors are nasal obstruction, local invasion of cranial nerves, serous otitis media, and cervical lymph node metastases. MRI is particularly well suited to complement the clinical examination in this situation. Other nasopharyngeal tumors, such as lymphoma, plasmacytoma, and occasionally rhabdomyosarcomas are also encountered. These tumors tend to be bulkier and infiltrate more widely than squamous carcinoma.

If a patient has symptoms of cranial nerve involvement, the skull base, jugular foramen, and the cavernous sinus should be thoroughly studied with MRI with administration of gadolinium. In particular, the direct coronal and sagittal MR scans are valuable to assess craniocaudal extension of tumor in skull

Figure 4 Maxillary sinus carcinoma. (a) Axial T_1 -weighted image shows opacification of the maxillary sinus with associated bone destruction. The amount of extension posteriorly is unclear. (b) Axial T_2 -weighted image at the same level shows improved muscle/tumor contrast. (c) Axial T_1 -weighted image at a higher level shows invasion of the pterygopalatine fossa. (d) Coronal T_1 -weighted image better defines the craniocaudal extension of the mass which involves the ethmoid sinus

base involvement, which can help to define radiation ports. Abnormalities of the skull base are detected by replacement of the normal low signal cortical bone and normal high signal bone marrow with the invading neoplasm.

The tensor veli palatini muscle is enveloped in a fascial plane of its own which divides the parapharyngeal space into two compartments.¹⁷ The tensor veli palatini muscle fascia passes posterior to the styloid process and divides the space into a lateral compartment which is called the pre-styloid space and a medial compartment which is called the post-styloid space. This helps narrow down the list of differential diagnosis, since depending on the anatomical location the possible pathologies are different. For example, the majority of pre-styloid space masses are salivary gland tumors, and most post-styloid masses are of neurovascular origin, such as neuroma and paraganglioma. Metastatic tumor can be seen in both compartments. The capability of multiplanar imaging and the far superior soft tissue resolution make MRI the clear imaging study of choice to evaluate the nasopharynx and the adjacent spaces.

7 TONGUE AND OROPHARYNX

In general, MRI produces superior soft tissue detail in evaluating the tongue and oropharynx compared with CT.^{18,19}

Lack of artifacts from dental amalgam and beam hardening artifacts from the mandible on MRI also eliminates two major shortcomings of CT in the examination of this area. Moreover, the ability of MRI to obtain direct coronal and sagittal scan planes is a distinct advantage in recognizing intrinsic tongue musculature and assessing tumor volume and spread for treatment planning. MRI is therefore considered the study of choice in this area.

Squamous cell carcinomas account for well over 90% of the malignancies of the tongue. The remaining lesions are lymphomas, rhabdomyosarcomas, adenocarcinoma, adenoid cystic carcinoma originating from the minor salivary gland, and an assortment of benign tumors and inflammatory processes.

Squamous cell carcinomas of the tongue, tonsillar bed and posterior pharyngeal wall are the lesions most likely to require radiological imaging. The main purpose of the MRI study is to evaluate the extent of the primary tumor and nodal spread. Occasionally an infiltrating tumor of these regions may have spread to the nasopharynx or the supraglottic larynx so that additional imaging is needed prior to surgical management.

The tongue is one area in the head and neck where T_2 -weighted pulse sequences are extremely valuable (Figure 6). The musculature of the tongue is of low signal on both T_1 - and T_2 -weighted images. Tumors produce a very high signal on T_2 -weighted images, resulting in excellent delineation of tumor margins. Anatomical details of the midline are best obtained by coronal T_1 -weighted images. The midline lingual septum

Figure 5 Nasopharynx carcinoma. This man presented with a neck mass. (a) T_1 -weighted axial image through the nasopharynx shows a right sided fullness. (b) T_2 -weighted image at the same level shows that the mass crosses the normal pharyngobasilar fascia and invades the parapharyngeal space. (c) Higher axial T_1 -weighted image shows the mass extending cephalad and involving the pterygopalatine fossa. (d) Axial T_1 -weighted image shows the large [presenting] posterior triangle lymph node

appears as high signal fibrofatty tissue separating the two lateral halves of the tongue. If the tumor crosses this midline, the relationship of the tumor margin to the lingual artery and hypoglossal nerve should be accessed.

At least one hypoglossal nerve and one lingual artery must be retained in order to perform a hemiglossectomy. A total glossectomy is a much more involved procedure for selected patients, and ideally requires specialized preoperative planning. The lingual artery is easily visible between the genioglossus muscle and the interdigitation of the styloglossus and hyoglossus muscles. Disruption of the diaphragm of the floor of the mouth (the mylohyoid muscle) in a bilateral fashion clearly indicates a far advanced tumor. Adenoid cystic carcinomas almost invariably extend along perineural lymphatics. In this case, gadolinium enhanced MRI is helpful to demonstrate the enhancement of the involved nerve.

Carcinomas of the base of tongue (posterior to the foramen cecum) are particularly troublesome. Because of their relative inaccessibility, they are usually not discovered until relatively late. Of these tumors, 76% are reported to have metastases at the time of initial examination. Nodal disease is frequently bilateral because of the bilateral lymphatic drainage of the posterior third of the tongue. Tumors of the base of the tongue have a propensity to spread laterally into the glossopharyngeal sulcus and tonsillar bed regions and anteriorly into the vallecula and preepiglottic space.

Since the mucosal surface of the base of tongue varies and asymmetry does not necessary indicate the presence of tumor,

the MRI finding which more strongly suggests the presence of an early base of tongue tumor is the disruption of the high signal intrinsic musculature. This is well visualized on axial and sagittal T_1 -weighted images. Sagittal images are particularly helpful in showing tumor extension to the supraglottic larynx.

The remaining anterior lesions of the cheek, retromolar trigone, alveolar ridge, and lips are readily visible by inspection or available to the palpating finger, and imaging studies are seldom necessary, except for advanced cases that require the investigation of deep extension.

8 LARYNX AND HYPOPHARYNX

Rarely does any radiological imaging modality play a significant role in reaching a diagnosis of malignancy in the larynx. The larynx is so readily accessible to clinical examination that the combination of biopsy and visual inspection usually strongly indicates the diagnosis of cancer. The very small true cord cancer may not be detected by MRI. While laryngoscopy can show mucosal surfaces and masses involving the lumen, deep extensions are difficult to detect from clinical examination alone, yet, in several areas, these extensions have profound implications on the management of disease.^{1,2,20-23} MRI to an even greater extent can define this important deep anatomy.

Figure 6 Tongue carcinoma. (a) Axial T_1 -weighted image shows an artifact from ferromagnetic dental work. Conventional dental amalgam does not create an artifact. (b) Axial T_2 -weighted image shows a small region of increased signal laterally which represents squamous carcinoma. It does not cross the midline nor invade the mandible. (c) Axial T_1 -weighted image following contrast shows enhancement of the lesion. The information is similar to that in the T_2 -weighted image. (d) Coronal T_1 -weighted image following contrast administration again shows the lesion

T_1 -weighted images with three scanning planes, axial, coronal, and sagittal, are ideal for the study of the larynx (Figure 7).^{2,20} It is valuable to start with sagittal images which show the level of true vocal cords. Axial images are obtained parallel to the true cord which is readily visualized in the paramedian sagittal image. Then coronal images are acquired perpendicular to the true vocal cord. This will provide improved delineation of three important anatomical divisions—the glottic, subglottic and supraglottic regions. T_1 -weighted sequences maximize contrast between the loose areolar tissue of the parapharyngeal and preepiglottic spaces, and most tumors. In addition, the laryngeal skeleton consists of several cartilages, which contain high signal marrow on T_1 -weighted images. The level of the true vocal cord can be identified by the intrinsic vocalis muscle attached to the vocal process of arytenoid cartilage, which rests on top of the cricoid lamina.²⁴

The supraglottic larynx consists of the laryngeal ventricle, the false cord, aryepiglottic folds, the epiglottis, and arytenoid cartilages. The supraglottic larynx is embryologically part of the buccopharyngeal anlage, and its lymphatic drainage is shared with the tongue, extending superiorly to the internal jugular chain. The preepiglottic space, anterior to the epiglottis, has a normal high signal which is displaced by low signal when tumors infiltrate this space.

The finding of the vertical spread of supraglottic tumors to the glottic region is even more important. Only advanced lesions spread down the inferior margin of the epiglottis to the

anterior commissure or from superior to inferior in the paralaryngeal space. For the treatment of supraglottic tumors involving the tongue base, a partial glossectomy may have to be performed in addition to the primary surgery.¹ Coronal and sagittal MRI scans with T_1 -weighted pulse sequences readily demonstrate these spreads. The true vocal cords and subglottic region act more like the trachea with the majority of the lymphatic drainage directed posteriorly and inferiorly.

Planning for any voice conservation laryngeal surgery depends on an accurate pre-operative knowledge of the precise extent of the disease within the larynx. Specifically, all techniques require an intact cricoid cartilage and at least one mobile arytenoid cartilage. MRI can provide this essential information. To plan this type of operation, the direct coronal and direct sagittal imaging capabilities of magnetic resonance far surpass axial CT images in the ability to define critical information regarding the cranial-caudal extent of the tumors. Compared to CT, MRI consistently shows superior soft tissue definition in cooperative patients. The use of direct coronal and sagittal scan planes allows the visualization of cranial-caudal tumor extension.

9 IMAGING GUIDED ASPIRATION CYTOLOGY

Imaging guided aspiration cytology has been applied to the nonpalpable deep sited head and neck lesion and has shown

Figure 7 Supraglottic larynx carcinoma. (a) Axial T_1 -weighted image shows a large right sided supraglottic mass. (b) The T_2 -weighted image at the same level shows similar findings but improved muscle/tumor contrast. (c) More cephalad axial T_1 -weighted image shows extralaryngeal spread to the adjacent neck. (d) Coronal T_1 -weighted image shows that the mass does not involve the cricoid cartilage of subglottic region

promising results. This was initially performed under CT or ultrasound guidance. Imaging guided aspiration cytology is now a standard procedure in the evaluation of head and neck tumors that cannot be sampled by more blind approaches. Aspiration cytology is now possible with MRI guidance using specially developed MRI compatible needles (E-Z-EM Corporation, Westbury, New York).²⁵⁻²⁸ The advantages of using MRI as an imaging guidance are lack of radiation, high soft tissue contrast allowing better delineation and detection of pathology, and multiplanar capability of showing the needle track in a single plane (see Figure 3).

Hemorrhage in the Brain and Neck Observed by MRI

Robert I. Grossman

University of Pennsylvania Medical Center, Philadelphia, PA, USA

1 HISTORY

Any new imaging modality that purported to compete with computerized tomography, in the late 1970s and early 1980s, had to be capable of detecting hemorrhage reliably. The success of MRI was intimately related to its ability for characterizing all stages of hemorrhage. Initially, at low imaging field strengths (up to 0.3 T), demonstration of acute hemorrhage (within the first 24–48 hours) was problematic at best.¹ With the introduction of higher field (0.5–1.5 T) MRI scanners in approximately 1984, it was clear that MRI could reliably image all stages of hemorrhage from the acute stage (within the first 3 days or so after the acute event) to chronic hemorrhages (those that occurred months to years following the event). Both the ability to recognize older hemorrhages and localize them precisely were major factors enabling MRI to become the primary imaging modality for the vast majority of hemorrhagic conditions affecting the central nervous system.

It is interesting to note the magnetic properties of dried blood had been first studied by Faraday almost 150 years ago.² Pauling and Coryell in 1936 recognized that deoxyhemoglobin was paramagnetic and oxyhemoglobin was diamagnetic.³ The T_1 relaxation mechanisms of solutions of methemoglobin were investigated by Davidson and Gold in 1957 and further elucidated by Koenig et al. in 1981.^{4,5} These studies were based on the Bloembergen et al. theory (1948) of ‘outer sphere’ relaxation of protons by paramagnetic centers.⁶

Thulborn et al. in 1982 observed that, at Larmor frequencies from 80 to 469 MHz, deoxyhemoglobin inside intact red blood cells (RBCs) would cause significant heterogeneity of magnetic susceptibility resulting in selective T_2 shortening.⁷ They also demonstrated that this phenomenon was proportional to the square of the magnetic field. De La Paz et al. attempted to characterize the MRI features of acute intracranial hemorrhage.⁸ They appreciated that the relaxation times of hemorrhagic tissue could be related to several interacting factors including red cell integrity, oxygen saturation, and hemoglobin concentration. Bradley and Schmidt in 1984 modeled subarachnoid hemorrhage on a spectrometer operating at 20 MHz and concluded that methemoglobin may be at least partially responsible for the observed high intensity on some magnetic resonance images.⁹ This was confirmed experimentally by Di Chiro et al. in an animal model of intraparenchymal hemorrhage.¹⁰ Gomori et al. unequivocally showed on a 1.5 T MRI scanner that a variety of different stages in the evolution of hemorrhage could be detected.¹¹ The gradient echo technique was initially utilized clinically by Bydder and Young in 1985 and then applied by Edelman et al. to increase the sensitivity to susceptibility differences, thus

improving the detectability of hemorrhage at all field strengths.^{12,13}

This review begins with the biophysical principles relevant to hemorrhage. These include a brief discussion of paramagnetism and magnetic susceptibility followed by structure of hemoglobin, the effect of protein on MRI signal intensity, and the importance of heterogeneity of magnetic susceptibility in the appearance of hemorrhage. The benefits and limitations of common imaging pulse sequences is then described. Lastly, we shall apply those principles to understand and interpret the diverse, yet characteristic, findings produced by blood on MRI.

2 BIOPHYSICAL PRINCIPLES

2.1 Paramagnetism and Magnetic Susceptibility

The magnetic moment of an electron is the result of its momentum and electric charge. Electrons have very large magnetic moments because of their light mass (~1/2000th of the proton’s mass). The term ‘magnetic dipole’ is applied to the electrons because of their north and south magnetic poles which are separated by a distance. Magnetic fields are induced by moving electric charges. Diamagnetic substances have paired electrons in their atomic and molecular orbitals. Paramagnetic molecules or atoms, on the other hand, contain unpaired orbital electrons. This produces a situation in which the magnetic moment of the unpaired electron is unopposed. Paramagnetic and diamagnetic molecules do not have magnetic fields of their own. In the absence of an external magnetic field, the electron dipoles of these substances randomly align, resulting in zero net magnetization. However, when placed in the magnetic field of an MRI scanner the electron dipoles of the paramagnetic substances line up in such a manner that the majority of the electrons point in the same direction as the external field. This results in augmentation of the external magnetic field. The ratio of the additional magnetic field strength to the strength of the applied magnetic field is termed the magnetic susceptibility of the paramagnetic substance. Magnetic susceptibility is thus a measure of how easily the substance may be magnetized.

Diamagnetic substances, which possess paired electrons, may still produce a magnetic field (when placed in an external magnetic field) by virtue of the fact that they are orbiting around the nucleus. This magnetic field is oriented to oppose the main magnetic field, and is called a Lenz field. It is far weaker than the field generated by the unpaired electron spins of paramagnetic substances. Paramagnetic substances, by virtue of having unpaired electrons, have the effect of magnetic susceptibility which augments the main magnetic field and also the much smaller effect of the Lenz field opposing the main magnetic field.

In the absence of unpaired electrons, protons relax (realign with the main magnetic field) by fluctuations in their magnetic fields caused by the motion of adjacent protons. Because of their large magnetic moments, unpaired electrons create fluctuations in local magnetic fields. These enable protons to realign faster with the external magnetic field producing a shortened T_1 relaxation time. This phenomenon is termed proton–electron dipole–dipole proton relaxation enhancement (PEDD PRE). In

order for this interaction to occur the water proton must come within 0.3 nm of the unpaired electron.

If a paramagnetic substance is nonuniformly distributed and the unpaired electrons are configured in a position such that water protons cannot come close (within 0.3 nm) to the unpaired electrons then the only interaction the water protons will appreciate is the locally increased magnetic field produced by the unpaired electrons (paramagnetic susceptibility). Protons will precess at a rate proportional to the local field strength which varies with the local susceptibility. The precession rate (Larmor frequency) is proportional to the local field strength. If a paramagnetic substance is heterogeneously distributed then the local field strength will vary throughout the region in which it is distributed. Protons, diffusing through these different areas of local field variation produced by susceptibility differences, will precess at different rates. Thus, protons sensing a slightly higher local field will precess more rapidly than those in a slightly lower magnetic field environment. The net effect is for the protons to develop phase differences with shortening of the apparent T_2 relaxation time (T_2 proton relaxation enhancement or T_2 PRE). The T_2 PRE occurs when there is a heterogeneous distribution of paramagnetic substances with diffusion of water protons.

In summary, paramagnetic substances enhance relaxation by two mechanisms, either PEDD PRE or T_2 PRE. The former requires the water protons to approach the unpaired electrons and produces shortening of both T_1 and T_2 ; however, the effect is predominantly noted as a T_1 effect. This relates to the fact that the T_1 relaxation rate ($1/T_1$) is much smaller than the T_2 relaxation rate ($1/T_2$). A paramagnetic relaxation effect added equally to either relaxation rate would contribute proportionally more to the much smaller term ($1/T_1$). Shortening of the T_1 relaxation time produces high intensity on the short TR /short TE (so-called T_1 weighted) images. The T_2 PRE produces low intensity on long TR images (so-called proton density and T_2 weighted images). Hypointensity from T_2 PRE can, at times, also be observed on T_1 weighted images. This is because there is a T_2 component to intensity even on a T_1 -weighted image, and substances with a very short T_2 (heterogeneously paramagnetic) can produce hypointensity on a T_1 -weighted image. The presence of susceptibility effects can be visualized by observing significant increases in hypointensity as the images become more T_2 -weighted (i.e. as the TE is increased).

2.2 Structure of Hemoglobin

Hemoglobin, the primary oxygen carrier in the bloodstream, is composed of four protein subunits weighing approximately 16 000 Da apiece. Each subunit contains one heme molecule consisting of a porphyrin ring and an iron atom which provides the binding site for oxygen.¹⁴ Binding of oxygen to the heme molecule of an individual subunit produces a conformational change in that subunit and adjacent subunits. The iron atom sits near the center of the porphyrin ring and is bound to one of the imidazole nitrogens of histidine-92. Molecular oxygen binds to the iron atom on the opposite side of the porphyrin ring.

In oxyhemoglobin, the oxidation state of the Fe is formally in the ferrous state which has six d orbital electrons. Molecular oxygen has two unpaired electrons. Oxyhemoglobin is diamagnetic, indicating that there must be pairing of the unpaired

electrons of molecular oxygen and the d electrons of the heme iron atom. Suffice to say that theories have been proposed to conceptualize the electronic state of oxyhemoglobin which are beyond the scope of this discussion.^{15,16}

There are four unpaired electrons in deoxyhemoglobin making it a paramagnetic molecule. When a hemoglobin subunit loses its oxygen molecule to form deoxyhemoglobin, the heme protein undergoes a small but significant change in its tertiary structure. The histidine ligand of the heme pulls the Fe^{2+} atom of deoxyhemoglobin out of the plane of the porphyrin ring and causes the porphyrin itself to dome. As a consequence, water molecules are unable to bind to the heme iron as they do in methemoglobin (see below), effectively preventing water from approaching close enough to the paramagnetic iron (<0.3 nm) to undergo PEDD PRE. However, deoxyhemoglobin can still produce local magnetic susceptibility changes (T_2 PRE).

Deoxyhemoglobin can be oxidized by one electron to methemoglobin by a number of different mechanisms. The Fe^{3+} is closer to the plane of the porphyrin ring in methemoglobin (in contrast to the Fe^{2+} atom of deoxyhemoglobin) so that water molecules can rapidly bind to the heme iron. Water must virtually bind to the heme iron in order to experience significant PEDD PRE. As the number of heme molecules is relatively small compared with the number of water molecules, this effect would be small except that the exchange rate of the water molecules is rapid relative to TR , allowing many water molecules to bind to the heme during the course of imaging. Normally an enzyme system within the RBCs rapidly reduces methemoglobin back to deoxyhemoglobin, but this process requires glucose and NADPH, which most likely are in short supply in sequestered hematomas.

2.3 The Effect of Protein

Hemorrhagic lesions generally contain significant concentrations of proteins. The effect of such protein is to slow the rotation of the water molecules. The much larger protein molecule has an intrinsically slower rate of rotation arising from Brownian motion due to its much larger mass. A strongly bound hydration shell of water molecules which surrounds the protein molecule with a zone of 'structured' water possesses slower rotational rates than the 'bulk' water molecules.^{17,18} In hemorrhagic situations the concomitant increased protein results in a greater number of water molecules rotating more slowly, and associated T_1 shortening. A physical correlate of the change in rotational rate that occurs with increasing the protein concentration is the increased viscosity of solutions with high protein concentrations (i.e. acute and subacute intraparenchymal hematomas). The rotational correlation time is a measurement of the time it takes for this rotation to occur. The T_1 relaxation time is noted to decrease with increasing protein concentration. At very high concentrations, the T_1 shortening produced by the addition of protein molecules plateaus. Slowing of the rotational rate of the water molecules by the addition of protein also produces a decrease in T_2 .

There are thus two major effects produced by the hemoglobin (deoxyhemoglobin or methemoglobin) molecule: (1) the paramagnetic effects secondary to the iron within the heme molecule and (2) the diamagnetic effects of the protein portion (apoprotein) of the hemoglobin molecule.

2.4 Heterogeneity of Hemorrhage

Heterogeneity of an RBC solution is proportional to $\text{Hct} \times (100 - \text{Hct})$, where Hct is the hematocrit. Thus heterogeneity would be maximal at $\text{Hct} = 50$ and nil at $\text{Hct} = 0$ or $\text{Hct} = 100$. Since the Hct of clot is ~ 90 , heterogeneity is present with a considerable susceptibility effect (36% of the maximal effect). Furthermore, retracted in vivo clot packs less efficiently and regularly than under experimental conditions. This further increases this predicted heterogeneity of magnetic susceptibility.

3 IMAGING PULSE SEQUENCES IN HEMORRHAGE

3.1 Spin Echo Imaging

The 90° rf pulse in a spin echo sequence rotates the protons into the transverse plane, and subsequently they precess at rates proportional to the field strength they sense. If there is heterogeneous distribution of paramagnetic molecules the protons will rapidly develop phase incoherence. This is because protons diffusing to different regions are experiencing varying magnetic strengths and precessing at slightly different rates. The 180° rf pulse in the spin echo sequence was designed to obviate local static magnetic inhomogeneities. The analogy is made to slow and fast runners that must reverse course half-way through a race so that all runners wind up at the finish line at precisely the same time. If, however, the protons diffuse randomly to different regions containing varying magnetic fields, then, the 180° rf pulse cannot rephase these diffusing protons to precisely the same location they had previously been at just prior to the pulse. This loss of coherence of the spins in the transverse plane results in the T_2 PRE and hypointensity on T_2 -weighted images.

The longer the interecho interval (the time between 180° pulses) the shorter the T_2 in regions of heterogeneous distribution of paramagnetic molecules. This is because the protons have more time to diffuse through different regions of varying field strengths when the interecho times are increased. Protons will thus lose phase coherence faster and have a shorter T_2 under conditions of heterogeneity of magnetic susceptibility and long interecho times. The selective shortening of T_2 varies as the square of the magnitude of the applied magnetic field, and the square of the variation in the magnetic susceptibility.

3.2 Gradient Echo Imaging

Gradient refocused echo images are more sensitive to susceptibility changes because the resultant local field gradients superimpose upon the applied phasing and rephasing gradients. The presence of local field gradients from some blood products adds linearly to the phasing and rephasing gradients. This leads to rapid dephasing of the protons and signal loss on these T_2^* -weighted images. This imaging technique is most sensitive for detection of heterogeneity of magnetic susceptibility but lacks some specificity with respect to particular hemorrhagic lesions. It is also problematic for routine imaging because of susceptibility differences at the skull base imposed by the air-tissue interfaces.

3.3 Fast Spin Echo Imaging

In the case of this pulse sequence there are up to 16 pulses of 180° per TR interval. This decreases the diffusion time of water protons and hence decreases the T_2 PRE. Susceptibility differences are decreased, and those elements of hemorrhage whose detection depends upon such differences (i.e. acute and chronic hemorrhage) become slightly more difficult to detect.¹⁹

4 CLINICAL SITUATIONS

4.1 Acute Hemorrhage

The biophysical effects just outlined sum to produce the appearance of acute hemorrhage as hypointensity on T_2 -weighted images. In a simple intraparenchymal hemorrhage, blood is extravasated into the brain parenchyma. The RBCs are isolated from the circulation and cannot be reoxygenated. The RBCs which initially contain oxyhemoglobin become desaturated. Oxyhemoglobin has no unpaired electrons and is not paramagnetic. Imaging a hematoma containing only oxyhemoglobin will be iso- or slightly hypointense on short TR images and hyperintense on long TR images. This is related to the water content in the serum of the extravasated blood. Occasional images of hyperacute hematomas (within a few hours after an ictus) have noted a rim of hypointensity on long TR /long TE images. This rim has been postulated to be the result of early accumulation of iron or deoxyhemoglobin.²⁰

Over hours the RBCs become desaturated. In addition, the inability of the isolated hematoma to rid itself easily of metabolic wastes with the possibility of increased lactic acid and CO_2 will tend to shift the oxyhemoglobin dissociation curve to the right (Bohr effect) which at any $p\text{O}_2$ will result in less hemoglobin saturation and more deoxyhemoglobin. Such desaturation can usually be appreciated very early following an ictus (within a few hours). The high protein content of the clot, as evidenced by the hyperdensity noted on CT, shortens T_1 relative to cerebrospinal fluid causing the hematoma to be hyperintense relative to CSF and isointense to the brain parenchyma on the short TR /short TE images (T_1 -weighted images). Since solvent water molecules are unable to approach close enough to the Fe^{2+} heme of deoxyhemoglobin, there is no additional T_1 shortening due to PEDD PRE interactions. On long TR /long TE images (T_2 -weighted images), the protein also shortens T_2 , rendering the clot hypointense relative to cerebrospinal fluid. Superimposed is a marked hypointensity secondary to susceptibility effects arising from the local field inhomogeneity produced by encapsulation of the paramagnetic deoxyhemoglobin within the RBCs. This effect is magnified on gradient refocused images, which as stated above are more sensitive to susceptibility effects. The end-result is the profound hypointensity of the acute hematoma on long TR /long TE and gradient refocused images (Figure 1). There is usually a penumbra of high intensity on long TR images surrounding the acute hematoma. This is a consequence of clot retraction with extrusion of serum into the surrounding normal brain and, later, the development of vasogenic edema (over days from the initial ictus). The high intensity of the surrounding edema and

Figure 1 Acute hematoma. (a) Short TR /short TE image of right cerebellar hemorrhage. This image was performed approximately 72 hours after the ictus. Note the hypointensity of the hematoma compared with normal cerebellum. There is a slight rim of hyperintensity representing methemoglobin which is just beginning to form at the periphery of the hematoma. (b) Long TR /long TE image of (a). There is striking hypointensity of the hematoma which is the result of heterogeneity of magnetic susceptibility due to deoxyhemoglobin in intact RBCs. Surrounding the hematoma is a penumbra of high intensity from serum and/or vasogenic edema

the mass effect of the hemorrhage should disappear within 4–6 weeks. If persistent high intensity remains surrounding the hemorrhage, then one should be suspicious of an intratumoral hemorrhage.

4.2 Early Subacute Hemorrhage

Within 3–7 days there is oxidation of the deoxyhemoglobin to methemoglobin inside of the RBCs, occurring initially at the periphery of the clot. Unlike deoxyhemoglobin, water molecules are able to approach within 0.3 nm of the paramagnetic heme of methemoglobin, permitting PEDD PRE interactions which shorten T_1 . It is this effect, in concert with the T_1 shortening from the high protein concentration, that gives methemoglobin its characteristic hyperintensity on T_1 -weighted images. Because the paramagnetic methemoglobin remains encapsulated within the RBCs, marked hypointensity is also seen on the long TR /long TE and gradient refocused images due to the same susceptibility mechanism described above for deoxyhemoglobin. The PEDD PRE interaction also shortens T_2 , but this effect is insignificant compared with the much larger susceptibility effects.

4.3 Mid Subacute Hemorrhage

The oxidation of deoxyhemoglobin proceeds centrally with time as evidenced by the development of hyperintensity within the center of the hematoma on the short TR /short TE images (Figure 2). Again the hematoma remains hypointense on the long TR , long TE and gradient refocused images due to susceptibility effects.²¹

4.4 Late Subacute Hemorrhage

Methemoglobin is less stable than deoxyhemoglobin, and the heme group can be lost spontaneously from the protein molecule. This free heme and/or other exogenous compounds (including peroxide and superoxide) can produce RBC lysis. Concomitantly there is protein breakdown and dilution of the remaining extracellular methemoglobin. Hyperintensity persists on the short TR /short TE images despite the decrease in the protein concentration due to the PEDD PRE of methemoglobin even at relatively low concentrations. The hematoma signal intensity increases on long TR /long TE images, approaching that of cerebrospinal fluid as there is loss of local field inhomogeneity upon RBC lysis as well as a decrease in the protein concentration. Also, the T_2 shortening effects of the paramagnetic heme due to PEDD PRE are rather small and unimportant except at the highest concentrations. Paralleling the breakdown of the methemoglobin is an accumulation of the iron molecules as hemosiderin and ferritin within macrophages at the periphery of the lesion which can be identified in the mid subacute stage of hemorrhage as well [Figure 2(b)].²² The iron cores of hemosiderin and ferritin contain ~2000 iron molecules ferromagnetically coupled to produce a ‘super paramagnetic’ substance which exhibits a very large susceptibility effect. The result is a black ring surrounding the lesion visible on short TR /short TE images but increasingly prominent on long TR , long TE spin echo and gradient refocused images.

4.5 Chronic Hemorrhage

After months, there is near complete breakdown and resorption of the fluid and protein within the clot. The iron atoms

Figure 2 Subacute hematoma. Same patient as in Figure 1 except approximately 7 days after ictus. (a) Short *TR*/short *TE* image revealing ring of high intensity. This high intensity from the PEDD PRE of methemoglobin is the hallmark of the subacute stage of hemorrhage. (b) Long *TR*/long *TE* image demonstrates a rim of low intensity representing peripheral hemosiderin. Free methemoglobin is observed inside the hemosiderin rim. In the centermost portion of the hematoma is deoxyhemoglobin. There is edema surrounding the hemosiderin rim

from the metabolized hemoglobin molecules are deposited in hemosiderin and ferritin molecules unable to exit the brain parenchyma due to an intact blood–brain barrier. The susceptibility effects of the ‘super paramagnetic’ iron cores of hemosiderin produce hypointensity on all spin sequences but

are most prominent on the long *TR*/long *TE* and gradient refocused images. There is no edema or mass effect associated with the hemorrhage. The methemoglobin (central high intensity) is gradually resorbed over months to years while the hemosiderin remains permanently in the brain. Very old hemorrhages often appear as slit-like cavities lined with hemosiderin and ferritin (Figure 3).

5 OTHER CLINICAL CONCEPTS

MRI is the technique of choice in virtually all hemorrhagic conditions of the head and neck. With its ability to detect hemorrhages of various ages, diagnosis of recurrent hemorrhagic events is facilitated. Conditions in which these situations are important include child abuse, siderosis of the central nervous system, and amyloid angiopathy.

It should be emphasized that the pO_2 of the hemorrhagic environs is important. Tumors are generally more hypoxic than normal brain so that an acute hemorrhage into a tumor may be more hypointense on long *TR* images because of increased amounts of deoxyhemoglobin. Conversely, in subarachnoid hemorrhage the red blood cells are bathed in the cerebrospinal fluid which has a pO_2 of approximately 43 mmHg. At this pO_2 , 72% of the blood is in the oxyhemoglobin form, and 28% in the deoxyhemoglobin state. As the amount of T_2 shortening varies as the square of the concentration of the paramagnetic $(0.28)^2 \times 100\% = 7.8\%$ of the T_2 shortening would be expected in this case when compared with that from 100% deoxyhemoglobin.²³ Thus, acute subarachnoid hemor-

Figure 3 Chronic hemorrhage. Coronal long *TR*/long *TE* image of an old right occipital hemorrhagic cavity delineates the hypointensity of hemosiderin lining the walls of the collapsed hematoma cavity. Note that there is no mass effect or edema associated with this chronic hemorrhage

rhage is the lone condition in which MRI is not the imaging technique of choice.

In general the vast majority of hemorrhagic lesions follow the continuum of MRI changes that have just been described. This makes MRI an elegant probe for most hemorrhagic conditions including intraparenchymal hemorrhage, intratumoral hemorrhage, traumatic hemorrhage, hemorrhagic cortical infarction, vascular dissection, venous thrombosis, and cavernous hemangioma.

1 INTRODUCTION

Despite the development of many effective antibiotic therapies and the evolution of new neurosurgical techniques, central nervous system (CNS) infections persist. Also the increasing, devastating effect of acquired immune deficiency syndrome (AIDS) has created a whole group of life-threatening opportunistic infectious diseases. CNS involvement usually occurs as a result of an infection from another organ system, or as a manifestation of a systemic disease. The brain, particularly, is well protected from invading agents by the calvarium, the meninges and the blood-brain barrier. However, different types of pathogens including bacteria, viruses, fungi, and parasites, can reach the brain by hematogenous spread (related to septicemia or endocarditis) and less likely by direct extension (bony erosion from an adjacent infected paranasal sinus, mastoid or middle ear). Other possible pathways for intracranial infections are via anastomotic veins from the face and scalp, along peripheral and cranial nerves (viruses) and after a penetrating head trauma.

Once in the intracranial cavity, pathogens can involve the parenchyma (cerebritis-abscess, encephalitis), the meninges (meningitis-ependymitis), and other extraaxial spaces (subdural and epidural empyemas). The brain's unique response to infection is due in part to the absence of draining lymphatics, the differentiation of vascular supply in gray and white matter, the presence of the blood-brain barrier, and the existence of perivascular cerebrospinal fluid (CSF) containing spaces (Virchow-Robin spaces). CSF assists in the dissemination of an infectious disease, acting as a perfect culture medium for microbial growth.

Magnetic resonance imaging (MRI) provides the most sensitive imaging modality to detect cerebral infection because of its optimal contrast resolution, the multiplanar imaging capability and the absence of signal from the surrounding bone. Intravenous contrast administration of gadolinium-diethylenetriaminepentaacetic acid (Gd-DTPA) increases the sensitivity of MRI and has allowed earlier detection of many infections compared to computed tomography (CT).¹ The only disadvantage of MRI is its poorer ability to detect calcifications, an important finding in some cerebral infections.

2 CEREBRITIS AND BRAIN ABSCESS

Cerebritis and abscess formation constitute a spectrum of the same process. Regardless of the pathogen, the brain tissue

reacts in a predictable way to focal parenchymal infection, developing initially an area of focal cerebritis, which consists of vascular congestion, petechial hemorrhage, and brain edema. Progression from the cerebritis stage to an encapsulated abscess with a central area of liquefied, necrotic material requires 10–14 days, although the rapidity of this process depends on patient's immunocompetence and the organism.² In the late mature abscess stage, when the collagenous capsule is fully formed, the surrounding edema decreases, and surgical drainage is facilitated. A brain abscess is usually caused by direct extension from an adjacent infected sinus or mastoid, or by hematogenous spread from an extracerebral source. Rarely is an abscess secondary to meningitis. In up to 20% of cases the source of infection is not discovered. In children the majority of cerebral abscesses are associated with cyanotic congenital heart disease. Anaerobic bacteria are isolated most frequently in the brain abscesses, although a mixture of pathogens are often found. Overall, in otherwise immunocompetent individuals, the commonest cultured organisms are *Staphylococcus* and *Streptococcus* species.³ Patients present usually in the late cerebritis-early abscess phase with nonspecific symptoms of headache, confusion, seizures or focal neurologic deficits. Fever and leukocytosis are common during the invasive phase of an abscess, but may resolve as it matures.

The MRI features of cerebritis-brain abscess depend on the stage of the infectious process at the time of imaging. In the early cerebritis stage MRI depicts the changes earlier than CT because of its superior sensitivity to alterations in water content. The area of cerebritis appears mildly hypointense on T_1 -weighted images. On the same sequence the early, subtle mass effect is best demonstrated. The infectious focus depicts high signal on T_2 -weighted images, both centrally from inflammation and peripherally from edema. As the infection matures, it increases in size due to an increase in edema and necrotic debris accumulates centrally, while the body attempts to isolate the infection by forming a capsule. The abscess capsule is thicker along the cortical surface because the vascularity of gray matter is much greater than that of white matter, resulting in increased local cortical reaction. The thinner portion of the capsule toward the white matter accounts for the predilection of abscesses to rupture into the ventricles producing ependymitis. At this stage of abscess formation, MRI demonstrates lengthening of T_1 and T_2 relaxation times in the core of the lesion. Peripherally there is moderate amount of vasogenic edema, which is mildly hypointense on T_1 - and hyperintense on T_2 -weighted images. On T_1 -weighted images, against the hypointense areas of the necrotic center and the surrounding edema, the abscess capsule stands out as an iso- or slightly hyperintense ring. On T_2 -weighted images the ring is markedly hypointense (Figure 1(a)). There is still discussion about the causes of capsular intensity. The hyperintensity on T_1 -weighted images is attributed to capsular hemorrhage by some authors. More recently the signal properties of the abscess capsule have been attributed to paramagnetic hemoglobin degradation products, or free radicals within macrophages. Macrophages are abundant in the capsule, and their activity is highest at the late cerebritis-early abscess phase, exactly when the signal intensity of the capsule on the T_2 -weighted images is particularly low.⁴

Contrast administration is very helpful in the evaluation of brain abscesses. Gd-DTPA produces mottled, heterogenous

Figure 1 Streptococcal abscesses. (a) Axial, T_2 -weighted (SE 2500/70) image shows the abscess capsules as hypointense rings surrounding the necrotic central core. There is also significant amount of peripheral edema. (b) Axial, postcontrast T_1 -weighted (SE 800/20, Gd-DTPA) image one week later demonstrates intense ependymal enhancement of the right lateral ventricle from the resulting ependymitis secondary to rupture of an abscess into the ventricular system. (Reproduced by permission of W. B. Saunders from R. R. Edelman and J. R. Hesselink (eds), *Clinical MRI*, 1990, Chap. 19, p. 578)

areas of enhancement in the cerebritis stage, with an enhancing rim developing as the abscess matures. The ring-like enhancement reflects the damaged blood-brain barrier and is typically smooth, well defined and thin walled. The ring is thinnest at its medial margin and often points to the adjacent ventricle. If an abscess ruptures into a ventricle and secondary ependymitis develops, there is enhancement of the ventricular wall, suggesting a very poor prognosis [Figure 1(b)].

Brain abscesses produced by nonpyogenic organisms typically occur in immunocompromised patients; these will be discussed in the section of AIDS-related infections.

3 MENINGITIS

Meningitis is an acute or chronic inflammation of the pia-arachnoid (leptomeninges) and the adjacent CSF. Patients with meningitis present with fever, headache, neck stiffness, photophobia, and altered consciousness. Acute meningitis (purulent) is usually caused by bacteria. The most common pathogens are *Haemophilus influenza*, *Neisseria meningitidis*, and *Streptococcus pneumoniae*.

Significant morbidity and mortality occurs with meningitis. The overall mortality rate ranges from 5% to 15% and severe, persistent neurologic deficits may be seen in 10–25%.⁵ In neonates and immunosuppressed patients Gram-negative meningitis is common, caused by *Escherichia coli*, *Pseudomonas aeruginosa* and *Klebsiella*. Viruses can also cause an acute meningitis (lymphocytic), particularly enteroviruses and the mumps virus. Viral meningitis is usually self-limited, with less significant symptoms and complications than those of bacterial origin.

Chronic meningitis is usually of tuberculous origin and presents as a long-standing, indolent process, in which vasculitis and cerebral infarctions from basal meningeal inflammation are more prevalent. In patients with an immunologic dysfunction, meningitis can be the result of fungal infection, with the main representatives being cryptococcosis, coccidiomycosis, and blastomycosis. Cryptococcal meningitis will be discussed in the section of AIDS-related infections. Finally, sarcoidosis is a noninfectious granulomatous disease that involves the CNS in 5% of patients, producing inflammation of the leptomeninges in the basal cisterns, the optic chiasma and the infundibulum. Other noninfectious processes which cause meningeal disease

and simulate infections are meningeal carcinomatosis, post-operative meningeal irritation, chemical meningitis, meningeal reaction adjacent to cerebral infarction, and subarachnoid hemorrhage.

Neuroimaging plays a limited role in the diagnosis of meningitis, which is made by history, physical examination and laboratory CSF findings. CT and MRI are mainly focused on the detection of associated complications, which include vascular thrombosis, infarctions, cerebritis-brain abscess, ventriculitis, hydrocephalus, empyemas of epidural and subdural space and subdural effusions. In case of uncomplicated acute meningitis, unenhanced MRI scans are usually unremarkable. More severe chronic cases may disclose hyperintense CSF on T_1 -weighted and proton density (PD) images in the basal cisterns secondary to obliteration from the inflammatory exudate and meningeal hyperemia. Contrast administration is very helpful in the evaluation of suspected meningeal infection because the involved meninges enhance diffusely and intensely. In the majority of cases of acute bacterial or viral meningitis, the meningeal enhancement occurs predominantly over the cerebrum, especially involving the frontal and parietal lobes, and the interhemispheric and sylvian fissures. However, in cases of tuberculous, fungal and sarcoid meningitis, the meningeal enhancement is more prominent in the basal cisterns (Figure 2). Gd-DTPA enhanced MRI appears to be much more sensitive than postcontrast CT in the detection of the meningeal enhancement, particularly when it occurs near the convexity.⁶ However, according to some authors, postcontrast MRI does not completely correlate with the extent of the inflammatory cell infiltration. Using animal models they have proved that above a threshold of inflammation, meningeal enhancement was visualized, but areas that exhibited mild meningitis histologically did not enhance.⁷ While more sensitive, postcontrast MRI is no more specific, in that any process that causes meningeal irritation can also cause meningeal enhancement.

In untreated or more severe cases of meningitis significant complications may occur in the following days or weeks. The exposure of the blood vessels to the inflammatory exudate may result in vasculitis and thrombosis, a common complication in cases of tuberculous meningitis. Occlusion of small perforating arteries results in focal infarcts in the basal ganglia, while involvement of larger vessels can produce massive infarcts. Multiple hemorrhagic infarcts in the white matter are the result of cortical venous or dural sinus thrombosis.⁸ Another severe complication of meningitis is cerebritis and brain abscess formation. Sometimes, rupture of a preexisting brain abscess into the CSF spaces can produce secondary meningitis. Ventriculitis and ependymitis can result from direct extension of an abscess, progression of meningitis, or from an infected intraventricular shunt. In cases of ependymitis, MRI exhibits increased periventricular signal on T_2 - and PD-weighted images, that often has a nodular and irregular character to distinguish it from transpendymal CSF flow associated with obstructive hydrocephalus. Also, on postcontrast scans ependymal enhancement outlines the ventricles. If purulent debris fills the ventricles, the CSF may give a higher signal than normal. It has been proved more accurate to compare the intraventricular CSF with the vitreous of the globe, since associated meningitis may prevent comparison with CSF of the basal cisterns.⁹ Another frequent complication of meningitis is either obstructive, or communicating hydrocephalus, which occurs secondary

Figure 2 Coccidiomycosis meningitis. Contrast-enhanced T_1 -weighted (SE 500/15, Gd-DTPA) axial (a) and coronal (b) scans demonstrate abnormal, extensive meningeal enhancement in the basal and ambient cisterns (arrows). (Reproduced by permission of the American Society of Neuroradiology from C. J. Wrobel, S. Meyer, R. H. Johnson, and J. R. Hesselink, *Am. J. Neuroradiol.*, 1992, 13, 1243)

to cellular debris obstructing the CSF pathways, or to arachnoid adhesions impairing extraventricular CSF flow and absorption. Ventricular dilatation may be the only abnormal finding in patients with meningitis and is adequately evaluated with both CT and MRI. Subdural collections can also complicate meningitis; these are discussed in the section on extraaxial empyemas.

4 ENCEPHALITIS

Encephalitis refers to a diffuse parenchymal inflammation of the brain caused primarily by viruses. Clinically, acute encephalitis should be suspected if the patient presents with convulsions, altered consciousness, delirium, aphasia, or ataxia. Particularly in herpetic encephalitis the symptoms reflect the propensity to involve the subfrontal and temporal lobes, with hallucinations, seizures, and personality changes. Viral encephalitis is usually acute, although it can occur from reactivation of a latent virus. The most common invading viruses are herpes simplex type 1 and type 2, herpes zoster, arbo- and enteroviruses, which produce almost the same reaction in brain tissue and appear similar on CT and MRI.¹⁰ In patients with AIDS, viral encephalitis may be caused by the human immunodeficiency virus (HIV), the cytomegalovirus (CMV) and the papovavirus (PML); these are discussed in the section on AIDS-related infections. Acute disseminated encephalomyelitis (ADEM) represents an immune-mediated complication following an antecedent viral infection, especially measles, mumps, rubella, varicella, or a preceding vaccination. Various forms of viral encephalitis (slow virus) are described in association with Creutzfeldt-Jacob disease and subacute sclerosing panencephalitis (SSPE). Finally, neonatal encephalitis is caused frequently by the group of TORCH pathogens (from the initials of toxoplasma, rubella, cytomegalovirus, and herpes simplex type 2) and share some common features like microcephaly, brain atrophy, hydrocephalus, and cerebral calcifications.

Herpes simplex virus type 1 (HSV-1) accounts for 95% of herpetic encephalitis in adults. The mortality rate approaches 70% and most of the survivors exhibit severe, persistent neurologic impairment. The virus usually invades the brain after reactivation of a latent form, which is frequently located in the trigeminal (gasserian) ganglion. The marked predilection for temporal lobe involvement supports the proposed theory that the infection spreads intracranially from the trigeminal ganglion along the meningeal branches of the trigeminal nerve. The resulting necrotizing encephalitis rapidly disseminates in the brain, sparing the basal ganglia and producing mass effect and edema as well as small petechial hemorrhages. Early diagnosis is paramount in order to institute effective medical therapy (vidarabine or acyclovir) and avoid devastating and irreversible brain damage. Definitive diagnosis of HSV-1 encephalitis is done after isolation of the virus from brain biopsy. However, given the appropriate clinical presentation, with or without MRI confirmation, treatment should be instituted immediately. In the early course of the infection the characteristic distribution is almost pathognomonic for HSV-1 encephalitis. By MRI, the early edematous changes appear as ill-defined areas of low signal on T_1 - and high signal on T_2 -weighted images, usually beginning unilaterally but rapidly progressing to both hemispheres (Figure 3). Variable mass effect and gyral

Figure 3 Herpes simplex encephalitis. (a) Sagittal, T_1 -weighted (SE 800/20) image shows area of low signal intensity in the right temporal lobe and frontal operculum. (b) Axial, T_2 -weighted (SE 2800/80) image demonstrates extensive hyperintense areas in the subfrontal and temporal lobes bilaterally, though more severe on the right hemisphere. (Reproduced by permission of W. B. Saunders from R. R. Edelman and J. R. Hesselink, (eds), *Clinical MRI*, 1990, Chap. 19, p. 584)

enhancement may also be present. Occasionally, foci of hemorrhage are visualized as areas of high intensity on both T_1 - and T_2 -weighted images.¹¹ Note that, unlike HSV-1, HSV-2 encephalitis, the most common neonatal viral encephalitis, is a panencephalitis without any predilection in the temporal lobes.

5 EXTRA-AXIAL EMPYEMAS

Accumulation of inflammatory debris may occur in the subdural or, less frequently, in the epidural space. Most of the extraaxial empyemas present acutely secondary to sinusitis or mastoiditis. Empyemas that occur secondary to an infected posttraumatic extra-axial hematoma or postcraniotomy cavity have a more prolonged and indolent course. Empyemas of the extra-axial compartments can also occur (particularly in infants) as complications of meningitis.

5.1 Subdural Empyemas

Pathogens may enter the subdural space via retrograde thrombophlebitis, via local dural erosion, or after contamination of a meningitis-induced subdural effusion. Most frequently, subdural empyemas are secondary to frontal sinusitis (40%).¹² Patients usually present with fever, seizures, focal neurologic deficit, or coma, and require urgent surgical and medical intervention. If completely or partially untreated, the empyema may be complicated with venous thrombosis, infarcts and parenchymal abscesses. The long TR , long TE sequence is the most sensitive in detecting small, crescentic fluid collections, especially when they are located near the inner table or along the falx. MRI can also distinguish subdural empyemas from subdural effusions or hematomas, depending on signal differences. T_1 -weighted images demonstrate the purulent collections as areas with more signal than pure CSF, due to the increased content of proteins and inflammatory debris. Subdural hematomas (subacute) can be easily distinguished because the extracellular methemoglobin exhibits markedly hyperintense signal on both T_1 - and T_2 -weighted images. MRI can also evaluate mass effect on the adjacent brain or CSF spaces, as well as the underlying parenchymal abnormalities.

5.2 Epidural Empyemas

In the case of epidural empyema, the purulent collection tends to localize outside the inelastic and firm dura, which protects the underlying brain from undesirable concomitant abnormalities. Thus, patients usually have a more silent clinical course. As with subdurals, MRI is the most sensitive method for the evaluation of epidural disease. The signal characteristics of the lentiform extraaxial collections are similar to subdural empyemas on both T_1 - and T_2 -weighted images. Mass effect on the adjacent brain can also be seen, usually without any evidence of parenchymal changes. On postcontrast scans there is profound enhancement of the inflamed dura, often thicker than that observed in subdurals.

6 CYSTIC LESIONS

Parasitic infections of the brain can commonly produce focal, cystic areas. We review the imaging features of the most frequent parasitic diseases with emphasis on neurocysticercosis. Toxoplasmosis is included in the section on AIDS-related infections.

6.1 Cysticercosis

This is the most common parasitic infection of the CNS in immunocompetent individuals and is caused by the pork tapeworm *Taenia solium*. Humans ingest the eggs with food contaminated by human or pig feces. In the stomach the eggs release embryos (oncospheres) which enter the intestinal wall and spread hematogenously, invading any human tissue and developing the larvae (cysticerci). Skeletal muscles and CNS are more frequently affected by cysticercosis. CNS infection is reported in 70–90% of cases and constitutes the commonest cause of seizures in young patients in developing countries with poor hygiene. Neurocysticercosis may involve the brain parenchyma, the ventricles, or the subarachnoid space. In parenchymal cysticercosis as the larvae initially invade the brain, they produce a mild inflammatory reaction, which on MRI can be demonstrated as focal, nonenhancing area of edema. Typically, at this very early, active stage of the disease, CT findings are unremarkable. In the next stage (3–12 months after infection) cystic lesions with thin walls and clear fluid are formed. They are usually located at the gray-white matter junction and appear as 1–2 cm spherical cysts with signal intensity identical to CSF on all MRI sequences (Figure 4). There is no evidence of associated edema or contrast enhancement. At this stage, a mural nodule (scolex), which is pathognomonic for cysticercosis, can be seen as a small (1–2 mm) focal, mural projection, isointense to the brain parenchyma. Visualization of the scolex is much easier with magnetic resonance than CT, due to the superior contrast resolution of MRI. Later on, as the parasites degenerate and die, they induce an inflammatory response with associated thickened cystic walls, increased signal intensity from the cyst's content owing to protein accumulation, marked surrounding edema and ring-like enhancement around the cyst. Finally, at the end-stage of the disease process, the cysts are completely mineralized and only punctate foci of calcifications may be seen. Obviously CT is more effective than MRI in the detection of calcifications, although specific MR sequences (gradient echo) are relatively sensitive to calcified lesions.¹³ Intraventricular cysticercosis occur in approximately 20% of cases. Cysts located near the aqueduct of sylvius or other CSF pathways can cause acute, obstructive hydrocephalus. The signal characteristics of the intraventricular cysts also follow CSF. Furthermore, on T_1 - and PD-weighted images, the cystic wall and the scolex can be more apparent against the adjacent ventricular CSF, even though the cystic component is indistinguishable from CSF.¹⁴ The unique feature in the ventricular variety of cysticercosis is that the degenerated cysticerci rarely calcify. In about 10%, cysticercosis may occur in the subarachnoid space, where the cysts have a racemose form and are larger, sterile, and usually without scoleces. Sometimes the only imaging finding is asymmetry of the CSF spaces. In the case of a profound inflammatory reaction, adja-

Figure 4 Parenchymal cysticercosis. (a) Noncontrast CT scan demonstrates multiple cysts in the brain parenchyma, several of which are calcified. (b) Axial, T_2 -weighted (SE 2500/70) image at approximately the same level, reveals high signal intensity within the cysts. Small calcified foci are difficult to identify, although the larger calcifications exhibit markedly low signal intensity. (Reproduced by permission of W. B. Saunders from R. R. Edelman and J. R. Hesselink, (eds), *Clinical MRI*, 1990, Chap. 19, p. 580)

cent brain abnormalities such as edema, gliosis, or communicating hydrocephalus can be seen.

6.2 Hydatid Disease

This is a parasitic infection which results from the ingestion of contaminated dog feces, containing eggs of *Echinococcus granulosus*. After ingestion, the eggs release embryos (oncospheres) in the gastrointestinal tract that spread hematogenously via the portal circulation to other human tissues. The majority of the lesions affect the liver and the lungs, although some can reach the brain (2–5%), where the larvae develop into large, unilocular cysts. Either CT or MRI can demonstrate adequately the large, commonly solitary cerebral hydatid cyst as a spherical thin-walled structure containing clear, sterile fluid with CSF imaging characteristics. Calcification of the cystic wall may occasionally occur and is better shown by CT. Hydatid (echinococcal) cysts are not associated with edema or contrast enhancement, except in case of cystic rupture and leakage, when an extensive inflammatory reaction is created.¹⁵

7 AIDS-RELATED INFECTIONS

Patients with AIDS often develop neurologic complications. At least 10% of all AIDS patients present with problems related to the nervous system, and more than one-third of them will manifest a clinically apparent neurologic disorder during the course of the disease.¹⁶ At autopsy it was revealed that 80–90% of patients with AIDS had neuropathologic abnormalities, and usually more than one disease process was present.¹⁷ AIDS is due to the HIV, which on the one hand damages the nervous system by direct infection (HIV encephalitis), and on the other produces immune system dysfunction, especially of cell-mediated immunity. The resultant immunodeficiency leaves the person with AIDS vulnerable to many opportunistic CNS infections. The most important and the commonest of these will be further analyzed below.

7.1 Toxoplasmosis

Toxoplasmosis is the most frequent opportunistic brain infection in AIDS patients. It is caused by the parasite *Toxoplasma gondii* which is an obligate intracellular protozoan. Patients may present with clinical manifestations of focal mass effect such as seizures, focal neurologic deficits, or cranial nerve palsies, as well as more generalized symptoms like headache, confusion, lethargy, and declining mental status. MRI is the most sensitive imaging modality, demonstrating lesions in patients with normal CT scans, particularly lesions at an earlier stage or located in the posterior fossa. Postcontrast MRI scans show multiple ring or nodular enhancing lesions surrounded by vasogenic edema and an associated mass effect. Toxoplasma lesions are typically located at the corticomedullary junction and the basal ganglia. Hemorrhage is uncommon. On T_2 -weighted images the lesions are either hyperintense or iso-

hypointense to brain parenchyma.¹⁸ The neuroimaging findings with both CT and MRI are not pathognomonic for toxoplasmosis and can also be seen in various infectious or noninfectious processes, such as brain metastases, intracerebral lymphoma, Kaposi's sarcoma, cryptococcoma, and tuberculoma. If the imaging studies are suggestive of toxoplasmosis and confirmatory toxoplasma titers are present, empiric antitoxoplasma medication is begun and the response of the treatment can be monitored with follow-up CT or MRI scans. If any or all of the lesions fail to respond to therapy by imaging criteria, toxoplasma may not be the causative infective agent, or there may be another, concurrent disease process present, and brain biopsy should be considered.¹⁹

7.2 Cryptococcosis

Cryptococcus neoformans causes the most common CNS fungal infection in AIDS patients, which in terms of relative frequency ranks third after HIV encephalitis and toxoplasmosis. It involves the CNS most commonly as a meningitis with minimal inflammatory response and extends mainly in the distribution of the perforating brain arteries and the perivascular (Virchow-Robin) spaces. On MRI there are four patterns: focal cryptococcomas; dilated Virchow-Robin spaces in the basal ganglia and midbrain; miliary enhancing nodules in the brain parenchyma and leptomeningeal-cisternal spaces; and a mixed pattern.²⁰

7.3 Other Brain Abscesses

Brain abscesses caused by nonpyogenic organisms typically occur in immunocompromised patients and share almost the same characteristics as the bacterial ones. Some of their unique features have been attributed to the diminished host response. Thus, multiplicity and extraparenchymal spread are frequently encountered. Tuberculous brain abscesses usually spread hematogenously from the lungs. They contain encapsulated pus with viable tubercle bacilli and differ from the more common tuberculomas (granulomas) which are smaller and contain caseous debris. Other associated lesions such as basal meningitis, multiple granulomas, and deep cerebral infarctions are very helpful clues to the diagnosis of tuberculosis.²¹ Another cause of non-bacterial brain abscess is fungal infections, which have recently increased substantially because of the large number of AIDS patients. The fungi may involve intracranial blood vessels, meninges, or the brain parenchyma (granulomas or abscesses). Fungal abscesses are caused primarily by *Aspergillus*, *Mucor* and *Candida* species, owing to their large hyphal forms which permit only limited access to the meningeal microcirculation. *Aspergillus* spreads to the brain hematogenously from the lung, gastrointestinal tract, or directly from the nasal cavity (paranasal sinuses). It readily invades vascular structures and causes hemorrhagic infarcts. In that case the resulting brain abscesses may mimic other hemorrhagic lesions such as metastases. CNS mucormycosis occurs in patients with compromised natural defense and uncontrolled diabetes and is spread by direct extension from adjacent facial compartments. Like *Aspergillus*, *Mucor* invades blood vessels and causes abscesses, more often at the inferior temporal and frontal lobes. Candidiasis may involve the brain parenchyma, producing multiple, scattered microabscesses.²²

Figure 5 HIV encephalitis. The axial, T_2 -weighted (SE 2500/70) image demonstrates multiple, ill-defined, hyperintense lesions in the periventricular white matter, becoming confluent in the right hemisphere. (Reproduced by permission of W. B. Saunders from R. R. Edelman and J. R. Hesselink (eds), *Clinical MRI*, 1990, Chap. 19, p. 590)

7.4 HIV Encephalitis

This is the most common CNS complication in AIDS patients, resulting in a progressive subcortical dementia with associated motor and behavioral abnormalities (AIDS dementia complex).²³ The hallmark of HIV encephalitis is the isolation of multinucleated giant cells and microglial nodules in the brain. Neither CT nor MRI are sensitive enough to detect those characteristic pathologic changes, showing only a nonspecific diffuse brain atrophy with a central predominance (ventricular enlargement). HIV leukoencephalopathy, which occurs in more severe cases of the encephalitis, is frequently located in the periventricular white matter and centrum semiovale. MRI depicts the white matter disease as extensive, nearly symmetric, ill-defined areas of high intensity on T_2 -weighted images, without any evidence of mass effect or contrast enhancement²⁴ (Figure 5).

7.5 CMV Encephalitis

CMV is a herpes virus which can reactivate in the immunosuppressed host and produce a necrotizing encephalitis and ependymitis. CNS infection by CMV is found in more than one-third of autopsies of AIDS patients. Pathologically, there is necrosis of the periventricular parenchymal tissue, associated with accumulations of enlarged cells containing the typical inclusion bodies of CMV. However, the correlation between clinical diagnosis and postmortem results is very poor in cases of CMV encephalitis, for three reasons: firstly, the signs and symptoms of the encephalitis are subtle and nonspecific; secondly, there is no characteristic CSF profile; and, finally, the neuroimaging findings are usually absent or nonspecific. PD- and T_2 -weighted magnetic resonance images may demonstrate a periventricular, thick, or nodular hyperintensity, which often involves the corpus callosum. CMV infection usually has a centrifugal spread from the ventricular ependyma involving diffusely the gray and white matter. On postcontrast scans there is diffuse subependymal enhancement around the lateral ventricles, representing the changes of ependymitis and making this an important differentiating point from HIV encephalitis or PML. The common simultaneous occurrence of both HIV and CMV viruses within the brain of AIDS patients supports

the proposed theory that an interaction between them may play a role in the pathogenesis of encephalitis in patients with AIDS. There is also some evidence from recent studies that CMV by itself has immunosuppressive properties which may compromise a patient's natural defense against HIV or other opportunistic pathogens.^{25,26}

7.6 Progressive Multifocal Leukoencephalopathy (PML)

PML is a progressive demyelinating disease of the brain, caused by reactivation of a latent papovavirus, and affecting 3–5% of all AIDS patients. The main target of PML is the oligodendrocyte which is the myelin-producing cell. The resulting demyelination develops a rapidly deteriorating clinical syndrome, with mental status changes, limb weakness, visual loss, or ataxia, and death usually ensues within 6 months. Initially, T_2 -weighted images demonstrate focal, round, or oval areas of high intensity which become larger and confluent with time. These areas are predominantly located in the white matter of the parieto-occipital region. However, involvement of the cortical gray matter, as well as the basal ganglia, the cerebellum, or the brainstem, is not uncommon.²⁷ Generally the lesions in PML do not enhance and there is no evidence of significant edema or mass effect (Figure 6).

Figure 6 Progressive multifocal leukoencephalopathy. (a) Axial, proton density (Fast SE 3600/17) image demonstrates area of high signal intensity in the subcortical white matter of the left, posterior temporal lobe. (b) Postcontrast, T_1 -weighted (SE 550/20, Gd-DTPA) coronal image discloses low signal intensity in the same region without any evidence of enhancement or mass effect

and

J. Randy Jenkins and Ronald A. Rauch

University of Texas Health Science Center, San Antonio, TX, USA

1 INTRODUCTION

Stroke affects 750 000 people annually in the USA and is the third leading cause of death.¹ However, only a small percentage of patients die as a result of stroke, making this the leading cause of disability and the third most costly disease affecting adults in this country.² Because many diseases can mimic ischemic stroke symptoms (epilepsy, migraine, tumor,

syncope, and psychiatric disorders), neuroimaging, particularly MRI with contrast injection, becomes essential for early diagnosis and prompt treatment.

2 ETIOLOGY OF STROKE

Ischemic stroke is the result of failure to perfuse and/or oxygenate the brain. This is usually caused by arterial occlusion. However, it may also be seen after systemic hypotension and/or hypoxia. The underlying pathophysiology during acute brain ischemia can be explained by the hypothetical ischemic models proposed by Virapongse et al.: complete ischemia (no perfusion) and incomplete ischemia (some perfusion).³ The MRI appearance and clinical outcome are usually distinctly different in these two ischemic models (Figures 1–4).^{4–6} Because of the paucity of collateral circulation, complete ischemia, caused by severe compromise of the arterial supply, generally involves most of the cerebral tissue supplied by the vessel and leads to complete infarction (Figures 1 and 2). Limited or no contrast agent can reach the ischemic tissue, thus early parenchymal enhancement is not expected. Incomplete ischemia, on the other hand, caused by a transient vascular

Figure 1 Complete ischemia in a 62-year-old man who presented with acute left hemispheric stroke symptoms. (a) Axial T_1 -weighted contrast-enhanced image (SE700/20) obtained 3 hours after onset showing abnormal arterial enhancement (AE) in the distribution of the left middle cerebral artery. No abnormal parenchymal enhancement (PE) is noted ($AE \propto 1/PE$). (b) The axial T_2 -weighted image (SE2200/90) at the corresponding level shows no parenchymal T_2 signal changes ($T_2\Delta$ values) at this time. (c) Axial T_2 -weighted image (SE2000/100) obtained 24 hours after (b) showing extensive T_2 signal changes consistent with ischemia of the left middle cerebral artery ($AE \propto T_2\Delta \propto 1/PE$). (Reproduced by permission of the American Society of Neuroradiology from W. T. C. Yuh, M. R. Crain, D. J. Loes, G. M. Greene, T. J. Ryals, and Y. Sato, *Am. J. Neuroradiol.*, 1991, **12**, 565)

Figure 2 Complete ischemia with an inverse relationship between arterial enhancement (AE) and parenchymal enhancement (PE). (a) Axial T_1 -weighted contrast-enhanced image (SE583/20) and (b) the corresponding T_2 -weighted image (SE2000/100) obtained within the first 24 hours of ischemic symptoms. Arterial enhancement (arrowed) is demonstrated in the distribution of the right middle cerebral artery (a). An intense signal on T_2 -weighted images ($T_2\Delta$ values) without parenchymal enhancement is present at this time (b). These findings are typical of complete ischemia expressed as $T_2\Delta \propto AE \propto 1/PE$. (c, d) Follow-up axial T_1 -weighted contrast-enhanced images (SE583/20) obtained 7 days after the onset of acute ischemic symptoms when arterial enhancement (AE) has completely resolved and significant parenchymal gyriform enhancement (PE) has developed ($PE \propto 1/AE$). (Reproduced by permission of the American Society of Neuroradiology from Crain et al.⁶)

occlusion (complete or partial), tends to produce a less severe ischemic insult and may be associated with a potentially reversible or minimal neurological deficit (Figures 3 and 4). Contrast material may be able to reach the ischemic tissue, and therefore early parenchymal enhancement is possible.

Watershed infarction has a somewhat different pathophysiological basis from that of complete or incomplete ischemia.⁴⁻⁶ This region is located at the edges of the vascular territory between major cerebral arteries (Figure 5). A decrease in perfusion pressure from either systemic hypotension or partial occlusion may therefore affect only the regions of the brain that have the most marginal blood supply. Watershed infarction is a hybrid of complete and incomplete ischemia in that collateral circulation and/or antegrade arterial supply are intact but inadequate. Despite the severe ischemic insult, contrast material can still be delivered to the ischemic tissue as in incomplete ischemia. The clinical outcome is less favorable, however, and is more characteristic of complete ischemic infarction.

3 ACUTE CEREBRAL ISCHEMIA

The MRI appearance of acute cerebral ischemia is dependent on several physiological factors (Table 1) that are often

Figure 3 Incomplete ischemia in a patient with transient neurological symptoms and early parenchymal enhancement. This patient developed transient left hemispheric symptoms after 2 minutes of test balloon occlusion of the left internal carotid artery. (a) Coronal T_1 -weighted contrast-enhanced image (SE538/20) obtained at 2 hours showing diffuse parenchymal enhancement (PE) (arrows) in the distribution of the left middle cerebral artery without arterial enhancement (AE) ($PE \propto 1/AE$). Also noted is enhancement of the caudate nucleus. (b) The axial T_2 -weighted images (SE2000/100) show no apparent signal change at this time. (c) Axial T_1 -weighted contrast-enhanced images (SE583/20) at 24 hours show no evidence of parenchymal or arterial enhancement. The resolution of parenchymal enhancement by 24 hours parallels the rapid neurological improvement in this patient. (Reproduced by permission of the American Society of Neuroradiology from Crain et al.⁶)

Figure 4 Incomplete ischemia with early, intense parenchymal enhancement (PE) in a patient who had a transient ischemic episode with right-sided weakness and aphasia that resolved almost completely in 2 hours. (a) Axial T_1 -weighted contrast-enhanced image (SE700/20) showing diffuse, intense cortical enhancement in the distribution of the left middle cerebral artery without evidence of arterial enhancement (AE) ($PE \propto 1/AE$). (b) The corresponding axial T_2 -weighted image (SE2000/100) shows a much less extensive area ($T_2\Delta$ values) of signal abnormality ($PE \propto 1/AE \propto 1/T_2\Delta$). (Reproduced by permission of the American Society of Neuroradiology from Crain et al.⁶)

Figure 5 Watershed infarction in a patient with severe neurological sequelae and early, intense parenchymal enhancement. (a) Axial T_1 -weighted contrast-enhanced image (SE516/20) showing early and intense parenchymal enhancement in the right posterior watershed zone without arterial enhancement. (b) Axial T_2 -weighted image (SE2000/100) showing an area of signal abnormality approximating the area of enhancement in (a). (Reproduced by permission of the American Society of Neuroradiology from Crain et al.⁶)

coexistent.⁵ Four types of MRI abnormality occur soon after an acute cerebral insult: (1) alteration in arterial blood flow, (2) parenchymal swelling, (3) parenchymal signal change, and (4) abnormal parenchymal enhancement.^{2,4,7-19}

Vascular flow abnormalities can be detected by MRI as an absence of flow void and/or abnormal arterial enhancement (Figures 1, 2, 6, and 7). Normal rapid flow in large arteries, such as the internal carotid or basilar arteries, typically produces a flow void on standard spin echo MRI, especially when studied with long TE pulse sequences. The loss of a flow void denotes thrombosis or abnormally slow flow (Figures 6 and 7).⁵⁻⁹ Although angiography is necessary to discriminate slow flow from thrombosis, the loss of flow void on MRI suggests cerebral vascular disease.

In certain cases, contrast enhanced MRI can further accentuate the underlying vascular flow abnormalities. On T_1 -weighted spin echo images ($TE \geq 20$ ms) obtained without flow compensation, arterial enhancement usually does not occur after the intravenous injection of paramagnetic contrast agents. In vessels where there is abnormally slow flow, caused either by

a high degree of stenosis or by occlusion without significant collateral supply, enhancement of arterial structures may be evident (see Figures 1 and 2).^{2,5,6,10,11} Although the absence of a flow void may represent either slow flow or thrombosis, arterial enhancement has been shown to correlate well with angiographic evidence of slow flow.¹² In cortical ischemia, patients with arterial enhancement typically have more severe clinical symptoms and a poorer outcome, whereas absent or minimal symptoms are usually seen in patients with evidence of cerebral ischemia without arterial enhancement. Although arterial enhancement occurs early, it generally lasts only about 1 week and seldom persists beyond 11 days (Figure 8).⁶ This contrasts with absence of flow void, which can be permanent.^{5,7-9} The disappearance of arterial enhancement probably indicates the reestablishment of rapid flow in the involved vessels and coincides with the 'luxury perfusion' demonstrated on computerized tomography or scintigraphy (occurring at 7–14 days). The early disappearance of arterial enhancement within 1 or 2 days has been seen in patients with transient ischemic attacks and coincides with the rapid resolution of the

Table 1 Pathophysiological Mechanisms for MRI Findings in Ischemia

Mechanism	MRI Findings	Possible causes	Estimated time (h) ^a
Flow kinetics	Absent flow void	Slow flow; occlusion	Immediately
	Arterial enhancement	Slow flow	Immediately
Biophysiological	T_1 morphological change (swelling)	Cytotoxic edema (free water)	2–4
	T_2 signal change	BBB breakdown; vasogenic edema; macro-molecular binding	8
	T_1 signal change	BBB breakdown; vasogenic edema; macro-molecular binding	16–24
Combination	Progressive parenchymal enhancement ^b	Impaired delivery of significant contrast agent	>120 ^c
	Early exaggerated enhancement ^d	Intact delivery of contrast agent; focal hyperemia	2–4

BBB, blood–brain barrier.

^aTime at which findings generally could first be detected by available MRI examinations; this does not necessarily imply the exact time of onset.

^bTypical findings in completed cortical infarctions.

^cUsually not detected before 5–7 days.

^dFound in cases with transient or partial occlusions and in watershed infarctions.

Figure 6 Arterial thrombosis in a 50-year-old man with symptoms of brain stem ischemia. (a) Parasagittal T_1 -weighted image (SE350/26) obtained 4 hours after the onset showing a linear signal isointense to brain in the prepontine region (arrows) along the course of the basilar artery, suggesting an intraluminal clot. (b) Axial T_2 -weighted image (SE2000/100) showing the absence of a flow void in the basilar artery (arrow). No apparent T_2 signal abnormality is detected within the pons at this time. (c) Repeat axial T_2 -weighted image (SE2000/100) obtained 48 hours after (a) showing the interval development of ischemic changes in the pons. (Reproduced by permission of the American Society of Neuroradiology from W. T. C. Yuh, M. R. Crain, D. J. Loes, G. M. Greene, T. J. Ryals, and Y. Sato, *Am. J. Neuroradiol.*, 1991, **12**, 565)

underlying proximal vascular disorder.⁶ Because watershed infarction usually has intact although insufficient blood flow, arterial enhancement is seen infrequently.

4 BRAIN SWELLING

Another early finding in ischemic stroke is brain swelling. Mass effect or brain swelling is probably caused by an abnormal accumulation of tissue water related to a complex combination of intra- and extracellular edema.⁵ This swelling can be recognized by the distortion of normal brain anatomy, with sulcal obliteration being the first observable sign of cortical ischemia (see Figure 7). T_1 -Weighted images offer the best definition of anatomy with minimal interference from cerebrospinal fluid and are generally superior for recognition of early swelling. Brain swelling often occurs as early as 2 hours before the onset of T_2 signal changes, presumably caused by cytotoxic edema (see Figures 3 and 7). This early (cytotoxic) edema primarily represents a shift of free water from the extracellular space into the intracellular space without an associated protein shift.

The swelling may then progress over several days, mostly caused by the development of vasogenic (interstitial) edema, and is associated with an abnormal signal on long TE sequences.^{5,13–18} In the early phase of acute ischemia, the signal change due to vasogenic edema is generally not observed until 8 hours⁵ (see Figures 1, 3, and 6), and is not fully developed until 24 hours after the infarction.^{5,19} The fact that the

signal change usually occurs after tissue swelling has begun supports the hypothesis of two phases of edema (cytotoxic and vasogenic). In transient ischemic attacks, swelling can be seen transiently on T_1 -weighted images without the development of T_2 hyperintensity.²⁰ In fact, reversible ischemia seldom is associated with major T_2 -weighted parenchymal signal changes. The absence of a T_2 signal change in cytotoxic edema is probably related not only to the small amount of free water shift (estimated at 3%) but also to the absence of a major change in the interactions between the water protons and the macromolecular proteins.^{5,15} Vasogenic edema, by comparison, is readily detected on T_2 -weighted images and usually becomes visible 8 hours after the onset of symptoms (see Figures 1, 2, and 6). It is associated with a significant amount of water and protein shift (exudate) from the intravascular space to the extracellular space. Because signal changes usually do not occur until 2 hours after the onset of the blood–brain barrier breakdown, appreciable signal changes detected by MRI may require a gradual accumulation of a sufficient amount of water in the extracellular space (the amount of water protons) as well as an alteration in the relaxation time of water molecules (the binding state of proton molecules). The maximal signal changes noted on T_2 -weighted images usually occur in 24–48 hours (see Figures 1, 5, and 6).^{5,21}

Signal changes are usually best seen on standard T_2 -weighted images. Abnormalities in the cortex or near the ventricle may be difficult to separate from the normal hyperintensity of adjacent cerebrospinal fluid. For this reason, the abnormal tissue signal may be easier to recognize on the

Figure 7 (a,b)

Figure 7 (c) Early development of brain swelling associated with complete ischemia in a 35-year-old woman. (a) Parasagittal T_1 -weighted nonenhanced images (SE450/20) obtained 2.5 hours after the onset showing signals isointense to brain in the prepontine cistern (arrow). (b) Corresponding parasagittal T_1 -weighted contrast enhanced images (SE450/20) obtained 40 minutes after (a) showing development of massive brain swelling in the occipital lobes (asterisk) and cerebellum and progression of a blood clot in the basilar artery (arrows). (Reproduced by permission of the American Society of Neuroradiology from W. T. C. Yuh, M. R. Crain, D. J. Loes, G. M. Greene, T. J. Ryals, and Y. Sato, *Am. J. Neuroradiol.*, 1991, **12**, 565)

first echo of a double-echo T_2 -weighted study, also referred to as a proton density weighted image.

5 ABNORMAL ENHANCEMENT FOLLOWING ADMINISTRATION OF A CONTRAST AGENT

Abnormal enhancement of cerebral tissue with intravenously administered gadolinium after an ischemic insult is associated with a breakdown of the blood–brain barrier and/or a loss of arterial autoregulation.^{4–6} Parenchymal enhancement usually occurs late in complete ischemia. During the acute phase of complete ischemia, severe arterial obstruction coupled with deficient collateral supply prevents both blood and contrast

Figure 8 Graph depicting the number of lesions that demonstrated arterial enhancement at the time of the initial MRI examination. Arterial enhancement frequently was detected within the first 24 hours, rarely after 7 days, and not at all after 11 days, suggesting the reestablishment of the circulation or development of collateral circulation. (Reproduced by permission of the American Society of Neuroradiology from Crain et al.⁶)

material from reaching the ischemic tissue (see Figures 1, 2, and 7). Therefore, no parenchymal enhancement is expected during the early phase of complete ischemia. By 5–7 days, the parenchymal enhancement will appear due to the reestablishment of the blood supply by recanalization of the occluded vessel and/or improved collateral circulation (see Figure 2). This reestablished blood supply will not only permit contrast material to reach the ischemic tissue, resulting in parenchymal enhancement, but also allow sufficiently rapid flow to cause the disappearance of arterial enhancement. This abnormal parenchymal enhancement will continue until the blood–brain barrier is reinstated with the maturation of the neovasculature, a process that normally takes several months after the infarction.²⁰

Early enhancement can be seen in either incomplete ischemia or watershed infarction (see Figures 3–5). In incomplete ischemia, the intact delivery of contrast material may allow for the possibility of early parenchymal enhancement (see Figure 2). We have seen parenchymal enhancement within a few hours after the onset of symptoms. Such enhancement is most likely caused by a loss of autoregulation or hyperemia and typically resolves on subsequent scans performed 24 hours later. Minimal or no T_2 signal abnormality develops. Similarly, in a watershed infarction (hypoperfusion with intact but inadequate blood supply), it is uncommon to see early parenchymal enhancement (see Figure 5). Unlike incomplete ischemia, however, the early enhancement observed in a watershed infarction does not indicate a favorable clinical outcome.

The complex relationship between the abnormal MRI findings, including extent of brain swelling (EBS), T_2 signal changes ($T_2\Delta$ values), arterial enhancement (AE), and parenchymal enhancement (PE), and clinical severity (CS) in acute ischemia generally can be expressed by the following formula:

$$CS \propto T_2\Delta \propto AE \propto EBS \propto 1/PE \quad (1)$$

This formula expresses the direct relationship between clinical severity, signal changes, extent of brain swelling, and arterial enhancement, which in turn have an inverse relationship to parenchymal enhancement.

The two exceptions that do not apply to equation (1) are the relationship between clinical severity in a watershed infarction and arterial enhancement in a small noncortical infarction. In a watershed infarction there is intact delivery of the contrast agent as in incomplete ischemia; however, it is insufficient. Therefore, despite the fact that the MRI findings suggest incomplete ischemia by equation (1), the prognosis and clinical severity are more like those of complete ischemia. The other exception is the lack of arterial enhancement in noncortical ischemia. Because the blood vessels involved in these types of infarction tend to be small, arterial enhancement usually is not seen. Nevertheless, the clinical severity of such cases may be quite grave.

6 NEW MAGNETIC RESONANCE MODALITIES

6.1 Diffusion MRI

Recent advances in MRI techniques now provide new information directly related to the underlying pathophysiology at

the cellular and microscopic levels and may allow the diagnosis of acute ischemia and estimation of infarction size. Diffusion imaging reflects abnormal water movement in acute ischemic tissues caused by the failure of the high-energy Na^+ -ATP pump and is sensitive to hyperacute ischemia within a few minutes after onset.²² In both animal models and clinical cases, early ischemic changes have been reported on diffusion imaging when standard T_2 -weighted imaging has shown no abnormalities.^{22,23} The abnormality in diffusion imaging is shown as a high signal intensity area. This increase in signal demonstrates a region of diminished net diffusion, which is dark on the apparent diffusion coefficient (ADC) images. The ADC is obtained from an exponential fit of the signal intensities of a series of diffusion imaging as a function of b factor. Diffusion abnormality can be identified at high b values. ADC changes are a sensitive marker of ionic equilibrium because they show a function of intra-extracellular water homeostasis.

In animal studies, the signal abnormality in diffusion imaging appears a few minutes after occlusion of the middle cerebral artery and enlarges over the next 24 hours.^{22,24} The abnormality in diffusion imaging is equivalent to that in T_2 -weighted imaging by 24 hours after the onset of ischemia;²⁵ however, cytotoxic and vasogenic edema may cause an overestimation of lesion volume. Kohno et al. reported regional correspondence of hyperintensity in diffusion imaging with perfusion deficits at cerebral blood flow (CBF) thresholds of 34 ml/min per 100 g tissue after 30 minutes and 41 ml/min per 100 g tissue after 2 hours of a major coronary artery occlusion.²⁶ Their reports suggest that the threshold for ADC changes at a given CBF depending on the duration of ischemia.

In clinical studies, diffusion imaging has also been reported to have a high sensitivity and specificity for acute ischemia. Lövblad et al. reported that the sensitivity and specificity of diffusion imaging in acute ischemic patients within 24 hours of onset were 88% and 95%, respectively.²⁷ However, the pathophysiological changes in acute ischemia in humans are likely to be more heterogeneous than those found in animal models. Human subjects reportedly have two phases in the time course of ADC changes: a significant reduction for 96 hours from stroke onset and an increasing trend from reduction to pseudonormalization to elevation at later subacute to chronic time points (> 7 days).²⁸

Previous reports do not conclude whether the diffusion imaging signal changes are indicative of reversibly or irreversibly injured tissue. The diffusion abnormality in global ischemia is reversible by early reperfusion within 12 minutes.²⁹ The regression of the diffusion abnormality was also reported in reperfusion models. Miyabe et al. indicated that if reperfusion occurred before ADC value decreased to approximately 70% or less of control values for 10–20 minutes, the ADC changes were usually reversible.³⁰ Ueda et al. suggested that diffusion imaging had the highest sensitivity but was not as specific as the regional cerebral blood volume (rCBV) map in predicting acute ischemic injury and tended to overestimate infarction size in patients studied within 72 hours of stroke onset.³¹ In addition, 25% (4 out of 16 lesions) of ADC abnormalities were false positives or reversible ischemia. These results may support the suggestion that the diffusion abnormality indicates early changes of both reversible and irreversible ischemia.

6.2 Perfusion MRI

Perfusion imaging provides direct information related to a reduction in blood flow that reflects the primary underlying pathophysiology of acute ischemia. Compared with the conventional spin-echo pulse sequence, echo-planar imaging is more susceptible to field inhomogeneity and is more advantageous in the evaluation of the T_2^* effect. The combination of dynamic echo-planar T_2^* -weighted imaging and intravenous bolus injection of contrast material produces hemodynamic information such as mean transit time (MTT) and CBV. Although perfusion imaging cannot produce absolute values but only semiquantitative data in estimating MTT and CBV maps, it can be performed quickly and has proven essential in the emergent management of patients with acute ischemic stroke. Furthermore, higher temporal resolution and multi-section images can be achieved by the echo-planar imaging techniques.

In an animal model, perfusion imaging demonstrated diminished perfusion within minutes of arterial occlusion.³² Perfusion imaging shows a signal or a delay in peak signal loss in the vascular distribution when an artery is occluded. In clinical studies, perfusion imaging was reported to be superior to diffusion imaging in the assessment of hemodynamic changes of chronic cerebral hypoperfusion. Maeda et al. indicated that ischemic tissue with prolonged regional MTT (rMTT) and a marked decrease in rCBV tended to suffer irreversible damage.³³ A mild decrease in rCBV with prolonged rMTT may suggest an area of reversible ischemia. A marked increase in rCBV may show the state of luxury perfusion in subacute ischemia.

Combined diffusion and perfusion imaging can provide more important information in the management of patients with acute ischemic stroke. The volume of ischemic tissue demonstrated by both diffusion and perfusion MRI has been reported to have a high correlation with neurologic outcome as measured by the National Institutes of Health (NIH) stroke scale, and these imaging techniques, therefore, can play a useful prognostic role in acute ischemic stroke patients (Figure 9).³⁴

Currently, the mismatch between diffusion and perfusion imaging in patients with acute ischemic stroke has been reported in several studies. Sorenson et al. studied patients within 10 hours of onset and showed that the abnormality in rMTT maps was larger than those in rCBV maps and diffusion imaging.³⁵ Rordorf et al. demonstrated that diffusion lesion volumes were smaller than the volumes of rCBV map abnormality in patients studied within 12 hours of onset, and the early CBV abnormality was slightly better than the diffusion abnormality as a predictor of final infarction size.³⁶ Röther et al. suggested that it was possible to differentiate between severely ischemic tissue and peri-infarct parenchyma by rCBV maps in hyperacute ischemia.³⁷ A recent report by Ueda et al. is similar to those reports in which the rMTT map overestimated the final infarction volume and the rCBV map provided the best estimation but differed in that their diffusion imaging underestimated final infarction volume.³¹ The size of the abnormality in diffusion and perfusion imaging depends on the imaging time from the onset of symptoms. Quantitative assessment of ischemic tissue viability and/or reversibility requires further study.

Figure 9 MRI within 12 hours in a 50-year-old male with acute onset of left hemiparesis. (a) Diffusion-weighted imaging; (b) apparent diffusion coefficient (ADC) map; (c) relative cerebral blood volume (rCBV); (d) relative mean transit time (rMTT) map. Both (a) and (b) demonstrate right hemisphere lesions in the middle cerebral artery distribution. The rMTT map (d) shows an area with hypoperfusion (arrow heads) that is much larger than that demonstrated by (a) and (b). The infarction core (arrow) may show the highest signal intensity (most severe hypoperfusion). In (c), the infarction core has a depletion of blood volume consistent with an inadequate collateral circulation (arrow)

6.3 MR Spectroscopy

Clinical application of MR spectroscopy (MRS) in the diagnosis and management of acute stroke has not been well established. There are several possible causes for the underutilization of spectroscopy in patients with strokes. (1) Most MR centers do not have sufficient scientific background and clinical expertise to facilitate such an application, and frequently avoid using such a technique. (2) The acquisition time for clinical MRS, which in the past has been long and not very reproducible, is not adequate for the management of acute stroke. (3) The diagnosis of acute stroke is usually quite

straightforward by the conventional clinical examination and radiological means. Consequently, clinical MRS is usually only applied for diagnosis of problematic cases. The capability of MRS in the assessment of tissue viability/reversibility has not been well established, although it may have great potential if the acquisition times can be shortened with improved techniques.

MRS provides a means to assess the biochemical characteristics of brain disease through direct and noninvasive assay of cerebral metabolites.^{38,39} Practically, phosphorus and protons are being measured in clinical applications for central nervous system disease. In ischemic brain tissue, MRS provides infor-

Figure 10 MRI examination of a 45-year-old patient with acute right side weakness: (a) T_1 -weighted image; (b) T_2 -weighted image. A rounded lesion at the left-periventricular region has hypointensity on the T_1 -weighted image (a) and hyperintensity on the T_2 -weighted image (b). This lesion does not demonstrate any contrast enhancement. Although the referring physician has high suspicion of acute stroke, the MR findings are not characteristic of acute stroke and are more consistent with a mass lesion. Proton spectra were obtained from normal parenchyma on the contralateral side (c) and from the lesion (d). This lesion shows a large lactate (La) peak and a diminished *N*-acetyl aspartate (NAA) peak at 1.3 and 2.0 ppm, respectively (d), compared with the normal tissue (c). (Ch, choline; Cr, creatine.) Follow-up MR examination obtained several months later demonstrated atrophy and gliosis at the same location, consistent with chronic infarction. In this particular patient, spectroscopy was valuable not only because it enabled surgical biopsy to be avoided, but also because it allowed a correct diagnosis for acute stroke

mation about energy status and oxidative metabolites related to the underlying pathophysiology (ischemia). Proton MRS is more effective because hydrogen atoms are more abundant than phosphorus in the brain parenchyma and proton MRS is easier to perform with the clinical unit.

There are two types of approach: localized and spectroscopic imaging (MRSI). Localized proton MRS methods can be separated into those with long and short echo times. Long TE (135 or 270 ms) acquisitions generally have proved easiest to use in clinical practice. Localization methods commonly

Figure 11 MRI examination 24 hours after a patient presented with acute stroke symptoms. (a) T_1 -Weighted and T_2 -weighted images were unremarkable. (b), Spectroscopic imaging of *N*-acetyl aspartate (NAA) did not demonstrate abnormality (area with decreased NAA). (c) Spectroscopy imaging of lactate showed an area of increased lactate in the right basal ganglia. (d) Follow-up spectroscopic imaging of NAA at 8 days demonstrated a focal area with decreased NAA at the right basal ganglia that was much smaller than the initial abnormalities demonstrated on the spectroscopy imaging of lactate (c) and was consistent with a focal infarction demonstrated on the T_2 -weighted imaging obtained at the same day (not shown). (e) Spectroscopy imaging of lactate at the same time again showed persistent elevations of lactate in the infarcted tissue. (Courtesy of Dr Nick Bryan, Diagnostic Radiology Department, NIH)

used in clinical proton MRS include depth-resolved surface coil spectroscopy (DRESS), point-resolved surface coil spectroscopy (SPARS), and the stimulated-echo method (STEAM).^{40–42} For practical purposes, STEAM allows for shorter echo times, thereby improving resolution of metabolites (e.g. myoinositol, glutamate, glutamine, and glycine).

Magnet designs have until recently favored the use of long TE sequences that are insensitive to eddy currents and can be easily implemented on the commercial scanner. Using long TE , the signal from most metabolites in the brain is lost except for that from four: choline, creatine, *N*-acetyl aspartate (NAA), and lactate. However, improvements in MRS techniques have

allowed short *TE* sequences taking 10–15 minutes; consequently these may realistically be incorporated into a routine imaging study without a significant time penalty.

The characteristic findings of a NAA and lactate peak can reflect the underlying pathophysiology of acute ischemia through a biochemical parameter. The NAA peak is attributable to its *N*-acetylmethyl group, which resonates at 2.0 ppm (Figure 10(c,d)). This peak also contains contributions from less-important *N*-acetyl groups. NAA is considered as a neuronal marker and is not present in tumors outside the central nervous system. Its concentration decreases with many diseases of the brain.⁴³ Similar to NAA, glutamate and *N*-acetylaspartyl glutamate are also localized in neurons. Glutamate is an excitatory neurotransmitter that plays a role in mitochondrial metabolism.⁴⁴ Glutamine plays a role in detoxification and regulation of neurotransmitter activities. These two metabolites resonate closely together and they are commonly represented by their sum as peaks located between 2.1 and 2.5 ppm. Breakdown of *N*-acetylaspartyl glutamate releases both NAA and glutamate, and subsequent breakdown of NAA leads to aspartate. The compounds are excitatory amino acids that increase with ischemia and cause 'toxic' effects, resulting in expanded tissue damage. Therefore, the concentrations of *N*-acetylaspartyl glutamate and glutamate may serve to monitor treatments designed to protect brain tissues by blocking excitatory amino acids.

The lactate peak has a special configuration and occurs at 1.32 ppm. It consists of two distinct, resonant peaks called a 'doublet' and is caused by the magnetic field interactions between adjacent protons (J coupling). Lactate levels of the normal brain parenchyma are low. The presence of lactate generally indicates that the normal cellular oxidative respiration mechanism is no longer in effect, and that carbohydrate catabolism is taking place.⁴⁵ Confirmation that a peak at 1.32 ppm corresponds to lactate may be obtained by altering the *TE*. At a *TE* of 272 ms, lactate projects above the baseline, whereas at a *TE* of 136 ms the lactate doublet is inverted below the baseline.

In humans, proton MRS performed within the first 24 hours after a stroke shows elevation of lactate, suggesting that anaerobic glycolysis is occurring as a result of ischemia (Figures 2 and 3).⁴⁶ Decreased NAA can be seen as early as 4 days after acute ischemia, suggesting neuronal loss (infarction) (Figures 10 and 11).⁴⁷ In chronic infarctions, there is a decrease in NAA, creatine, and choline, but no evidence of lactate.⁴⁸ Experimentally, an increase in lactate may be detected after only 2 to 3 minutes of cerebral ischemia.⁴⁹ In these animals, the lactate returned to normal when the underlying ischemia was reversed. In the evaluation of human hyperacute cerebral infarction, shortening of examination time as well as the better tolerance of the motion artifact will be needed in order to make spectroscopy a realistic tool in the management of the stroke patient.

The age-related white matter changes contain normal levels of NAA and creatine⁵⁰ but do not contain lactate. The increased choline levels are suggestive of an alteration of the white matter phospholipids.

7 CONCLUSIONS

An understanding of the spectrum of MRI findings in acute ischemia may facilitate a correct diagnosis of stroke, particularly in the hyperacute stage, and allow differentiation from

other etiologies. Recent advances in diffusion and perfusion MRI indicate a potential for providing important information concerning factors that determine tissue viability and/or reversibility; this will assist clinical decisions in selecting the appropriate patients for thrombolytic therapy.

Magnetic Resonance Imaging of White Matter Disease

Donald M. Hadley

Institute of Neurological Sciences, Glasgow, UK

1 INTRODUCTION

1.1 Characteristics

The white matter of the brain constitutes the core of the hemispheres, brainstem, and cerebellum. It is composed of axons, which transmit chemically mediated electrical signals, and glial supporting cells set in a mucopolysaccharide ground substance. The glial cells—oligodendrocytes, astrocytes, ependymal cells, and microglia—account for about half the brain's volume and 80–90% of its cells. The oligodendrocytes provide an insulating sheath of myelin by invagination, wrapping concentric layers of their cell membrane around the axons. Astrocytes are now known to influence and communicate through their long foot processes, which are in intimate contact with capillaries, neurones, synapses, and other astrocytes. The ependymal cells form the lining of the brain's internal cavities, while the microglia, normally relatively inconspicuous, are capable of enlarging and becoming active macrophages.

The white matter fibers are grouped into location-specific tracts, which can be divided into three main types:

- (a) projection fibers that allow efferent and afferent communication between the cortex and target organ;
- (b) long and short association fibers, which connect cortical regions in the same hemisphere; and
- (c) commissural fibers, which connect similar cortical regions between hemispheres.

The formation and maturation of axons has been reviewed by Barkovich et al.¹ After development of the axons and their synapses, the final process of myelination occurs. This is crucial to the appearance on MRI.

1.2 Evolution and Imaging

The contrast obtained between gray and white matter is largely due to the myelination of the white matter tracts. Myelin is composed of a bilayer of lipids (phospholipids and glycolipids), cholesterol, and large proteins. In 1974, Parrish et al.² showed differences in the relaxation times of gray and white matter by spectroscopy before imaging was possible. These differences were later confirmed by MRI. In white matter, the myelin lipids themselves contain few mobile protons visible to routine MRI, but they are hydrophobic, and therefore, as myelination progresses, there is loss of brain water and a decrease in T_2 signal. Cholesterol tends to have a short T_1 , and the increased protein also decreases the T_1 of water. This results in

white matter having a reduced intensity on T_2 -weighted images and increased intensity on T_1 -weighted images compared with unmyelinated fibers or gray matter.

Myelination of the white matter is first noted in the cranial nerves during the fifth fetal month, and continues throughout life.³ By birth, myelination is present in the medulla, dorsal midbrain, cerebellar peduncles, posterior limb of the internal capsule, and the ventrolateral thalamus. In general, myelination is completed from caudal to cephalad, from central to peripheral, and from dorsal to ventral. Key landmarks include the pre- and post-central gyri, which are myelinated at one month, with the motor tracts completed by three months. At this time, myelination is completed in the cerebellum, and progresses through the pons in the corticospinal tracts, cerebral peduncles, the posterior limb of the internal capsule, and up to the central portion of the centrum semiovale, to be completed by six months. The optic radiations and the anterior limb of the internal capsule are myelinated by three months. Myelination in the subcortical white matter is first noted in the occipital region at three months, and proceeds rostrally to the frontal lobes. This posterior-to-anterior maturation is noticeable in the corpus callosum, with the splenium first showing myelin at four months, progressing to the genu, where it is complete at six months.

This normal development is best visualized by MRI with age-related heavily T_1 -weighted (e.g., inversion–recovery) sequences for the first six months, by which time the appearance is close to adult; after this, T_2 -weighted sequences are most helpful, with all the major tracts assuming an adult appearance by 18 months. The cause of these differences is not fully understood, but is thought to be related to the initial hydrophilicity, with its associated increase in hydrogen bonding with water. Next, the T_2 shortening may be caused by the subsequent tightening of the myelin sheath, further redistributing the free water components. It has been shown that the very earliest changes of myelination are shown better by diffusion- or fluid-attenuated T_2 -weighted sequences than by conventional T_1 - or T_2 -weighted sequences.^{4,5} It must be noted, however, that some areas around the trigones of the lateral ventricles may not fully myelinate in normal children until they are 10 years old.

1.3 Classification of Abnormalities

There are a bewildering number of white matter diseases with multiple etiologies and pathological mechanisms. Although MRI is very sensitive to any white matter abnormality, it is rarely possible for the radiologist to make a specific diagnosis.⁶ It is, however, useful to divide them into three main groups:

- (a) a dysmyelinating group in which there is a biochemical defect in the production or maintenance of normal myelin; some of the individual enzyme deficiencies have been identified and will be discussed below;
- (b) a demyelinating group in which myelin is formed normally but is later destroyed;
- (c) a vascular group in which normally myelinated white matter is destroyed by a critical reduction in blood flow to a particular region; this may also involve the adjacent gray matter or a large segmental part of the brain, depending on

the extent and severity of the reduction in blood flow and the susceptibility of the cells involved.

In many of these conditions, the diagnosis is biochemical, but the radiologist has an important role in suggesting the diagnosis, and documenting progression, response to therapy, or complications.

2 DYSMYELINATION DISEASE

2.1 Leukodystrophies

These are diseases where dysmyelination occurs as a result of the production and maintenance of abnormal myelin. Becker⁷ and Kendall⁸ have produced excellent reviews of this subject.

2.1.1 Alexander's Disease (*Fibrinoid Leukodystrophy*)

This usually presents in the first few weeks of life with macrocephaly and failure to attain developmental milestones. There is progressive spastic quadriplegia and intellectual failure. Death ensues in infancy or early childhood, although cases have been reported in adolescents and adults. An enzyme defect has not yet been identified.

MRI shows increased T_1 and T_2 relaxation times, starting in the frontal lobes, and progressing to the parietal and capsular regions.^{9,10} With the accumulation of Rosenthal fibers around blood vessels, there may be disruption of the blood-brain barrier, producing frontal periventricular enhancement. Frank cystic changes develop in the frontal lobes in the later stages, with atrophy of the corpus callosum.

2.1.2 Canavan's Disease (*Spongiform Leukodystrophy*)

This is a lethal autosomal recessive neurodegenerative disorder of Jewish infants caused by a deficiency of aspartoacylase. The disease progresses with marked hypotonia, macrocephaly, seizures, and failure to attain motor milestones in the first few months of life, although sometimes it starts as early as a few days, progressing to spasticity, intellectual failure, and optic atrophy. Death usually occurs in the second year of life. The radiological features may be seen before the full clinical picture has developed, but the diagnosis depends on the biochemical testing.

The demyelinated white matter shows increased T_1 and T_2 relaxation times, preferentially in the arcuate U fibers of the cerebral hemispheres. The occipital lobes are more involved than the frontal, parietal, and temporal lobes. Initially, it may spare the corpus callosum, deep white matter, and internal and external capsules, but, as it progresses, diffuse white matter involvement occurs, which leads to eventual cortical atrophy.¹¹

2.1.3 Krabbe's Disease (*Globoid Cell Leukodystrophy*)

This is a rare, lethal, autosomal recessive leukodystrophy (locus now mapped to chromosome 14) due to a deficiency of the first of the two galactocerebroside β -galactosidases. This arrests the normal breakdown of cerebroside, disrupts the turnover of myelin, and results in the accumulation of galactosylsphingosine. This is toxic to oligodendrocytes, and causes a marked loss of myelin, although the minute amount of

myelin remaining is normal. Changes become evident between one and six months old, although it is occasionally noted earlier, and leads to death within one to three years. The clinical diagnosis is based on an assay of β -galactosidase from leukocytes or skin fibroblasts.

Early in the disease process, MRI can be normal¹² and a spectrum of lesions then develops over several months. These are nonspecific symmetrical patchy changes in the periventricular white matter similar to many other demyelinating diseases such as multiple sclerosis, with increased T_1 and T_2 signals.^{8,13} The thalami, central white matter, and cerebellar white matter may show decreased T_1 and normal or slightly decreased T_2 signals.¹⁴ These changes are reflections of the increased attenuation sometimes seen on computerized tomography (CT), and are probably the result of paramagnetics such as crystalline calcification. In advanced disease, there is diffuse cerebral atrophy.¹²

2.1.4 Pelizaeus-Merzbacher Disease

This term has been used to cover the five subtypes of sudanophilic leukodystrophy,¹⁵ but here it will be taken to mean the slowly progressive X-linked recessive leukodystrophy. The dysmyelination is now thought to be due to a point mutation in the PLP gene coding for the myelin-protein proteolipid protein. It presents in infancy, and runs a very chronic course leading to death in adolescence or early adulthood.

On MRI, there is a general lack of myelination without white matter destruction. The brain has the appearance of the newborn, with high signal intensity only appearing in the internal capsule, optic radiations, and proximal corona radiata on T_1 -weighted images, and practically no low signal in the supratentorial region on T_2 -weighted sequences.¹⁶ A 'tigroid' pattern consisting of normal myelinated white matter within diffuse dysmyelination can be seen later on T_2 -weighted sequences. When severe, there may be a complete absence of myelin. Cortical sulcal enlargement may be seen.

2.1.5 Metachromatic Leukodystrophy

The commonest of the sphingolipidoses is due to a deficiency in the activity of arylsulfatase A. This enzyme is responsible for normal metabolism of sulfatides, which are important constituents of the myelin sheath. The disease is subdivided into:

- (a) neonatal, with a rapid downhill course leading to early death;
- (b) infantile, presenting between one and four years with polyneuropathy, ataxia, progressive retardation, and spastic tetraparesis;
- (c) juvenile, with dementia¹⁷ and behavioral disorders progressing to spastic tetraparesis;
- (d) the rare adult type, presenting at any age with dementia and spastic paraparesis.

The imaging findings are nonspecific, with symmetrical areas of increased T_1 and T_2 relaxation times in the centrum semiovale, representing progressive dysmyelination and gliosis within areas of normal myelination. The peripheral white matter, including the arcuate U fibers, is spared until late in the disease. As there is no inflammation, enhancement is not a feature. These appearances allow differentiation from the gross lack of myelination seen in Pelizaeus-Merzbacher disease. As

the disease progresses, brain atrophy becomes more prominent than the white matter signal changes. Proton MRS may have a clinical role in the diagnosis.¹⁸

2.1.6 Adrenoleukodystrophy (Childhood Type: X-Linked)

This is seen exclusively in males, and was thought to be due to a deficiency of acyl-CoA synthetase. Long-chain fatty acids are incorporated in cholesterol esters, replacing the normal nonesterified cholesterol. It usually presents between the ages of five and ten years, with a disturbance of gait and intellectual impairment, with fairly rapid progression and the development of hypotonia, seizures, visual impairment, and bulbar symptoms. Neurological complaints are classically preceded by adrenal insufficiency and skin pigmentation, which may be precipitated by an intercurrent infection; however, they sometimes may never appear.

Symmetrical long T_1 and T_2 signals are usually first seen in the peritrigonal regions extending into the splenium of the corpus callosum. Although typical, these may rarely be seen in other white matter diseases such as Krabbe's. These signal changes gradually extend to involve the occipital lobes and more anterior regions such as the medial and lateral geniculate bodies, thalami, and the inferior brachia. The pyramidal tracts and the occipito-temporo-parieto-pontine fibers show progressive alteration, with sparing of the fronto-pontine fibers in the medial part of the crus cerebri. The lateral lemnisci and the cerebellar white matter may also become involved. Although this is the usual pattern, atypical symmetrical or asymmetrical involvement of other lobes sometimes occurs¹⁹ (Figure 1).

Three zones of abnormal long T_1 and T_2 signals can be recognized:

- (a) a central region of gliosis with necrosis and cavitation, next to
- (b) an intermediate region of active inflammatory demyelination that shows enhancement due to blood-brain barrier breakdown, surrounded by
- (c) a peripheral less marked zone of demyelination without inflammatory reaction.

As the disease progresses, atrophy becomes the more dominant feature on MRI.⁸

2.1.7 Adrenoleukodystrophy (Adrenomyeloneuropathy—Adult Type)

This often presents in the same family as the childhood type, but occurs in adult life. It is caused by a similar enzyme defect. The abnormal myelination is most marked in the corticospinal and spinocerebellar tracts, but can extend into the brainstem, involving the pyramidal tracts running into the posterior limb of the internal capsules, and the frontopontine and occipito-temporo-parieto-pontine fibers. The cerebellar white matter is usually affected, with sparing of the cerebral white matter. MR changes usually appear late in the course of the disease.

2.1.8 Adrenoleukodystrophy (Neonatal)

Several disorders have been grouped under this heading, but with active research at present underway, the classification of the enzyme defects may change. Severe progressive neurological impairment occurs, with psychomotor retardation,

Figure 1 Adrenoleukodystrophy: (a) T_2 -weighted and (b) gadolinium-enhanced T_1 -weighted sections of a five-year-old boy showing bilateral focal areas of white matter abnormality with marginal enhancement (biopsy-proven)

dysmorphic facial features, hypotonia, seizures, and defective liver function. In contradistinction to the childhood type, these abnormalities are present from birth. The enzyme defect may be confined to fatty acyl-CoA oxidase resulting in defective very long chain fatty acid oxidation.

There is diffuse degeneration of cerebral white matter, causing atrophy at a very early age. Progressive MRI changes have

been described²⁰ in a single case followed for three years, with delayed myelination followed by symmetrical demyelination of the corona radiata, optic radiations, and pyramidal tracts.

2.1.9 Phenylketonuria

This is an autosomal recessive metabolic encephalopathy due to a defect in phenylalanine hydroxylase conversion of phenylalanine to tyrosine, resulting in hyperphenylalaninemia. Strict dietary restrictions must be maintained from early infancy to prevent profound mental retardation. Other cofactor defect variants may result in lesser or greater degrees of encephalopathy.²¹ When there is a defect of dihydropteridine reductase, there are severe neurological and cognitive abnormalities in spite of adequate dietary restrictions. Severe white matter changes have been noted,²² with cystic degeneration and loss of parenchyma.

Subtle abnormalities of white matter have been shown by MRI in older children and adults who have classical phenylketonuria despite having maintained a degree of dietary restriction.^{23,24} This possibly provides some evidence for continuing the restrictive diet and phenylalanine-free protein supplements and into adulthood.²⁵

Varying degrees of periventricular white matter abnormality have been shown, with focal and diffuse lengthening of T_1 and T_2 relaxation times most easily seen on the T_2 -weighted images (Figure 2). In some studies, these changes were found to correlate loosely with the adequacy of the reduction and maintenance of serum phenylalanine levels,^{25,26} while other workers showed no clear relationship.²⁴

Figure 2 Phenylketonuria: T_2 -weighted section showing subtle white matter hyperintensities in the optic radiations in spite of apparently adequate dietary control in a 13-year-old

2.2 Miscellaneous

Over 600 individual dysmyelination disorders that may affect MRI appearances have been identified in childhood alone. Continuing research is progressively isolating the individual enzyme or gene defects, which will in time allow more specific classification. Meanwhile, the following less well defined groups of disorders will be considered.

2.2.1 Neurodegenerative Disorders

These occur in a number of devastating developmental disorders of childhood, which are either congenital or acquired. Clinical findings are usually nonspecific, and laboratory tests have to be selected carefully. Imaging demonstrates the results of abnormal cellular function on parenchymal morphology. MRI is sensitive, but specificity is limited, and it must be integrated with the other clinical findings. Proton MRS may be able to detect abnormal metabolite levels and allow an earlier and more specific determination of neurodegeneration.²⁷

2.2.2 Lysosomal Disorders

Several of these have been mentioned under specific enzyme defects above, such as metachromatic leukodystrophy and Krabbe's disease. All lack activity of a specific lysosome enzyme, which is inherited in an autosomal recessive manner except Hunter II, which is X-linked. Abnormal materials build up in the lysosomes. The CNS is affected directly or secondary to the metabolic abnormality in adjacent structures.

Dysmyelination is shown as an increase in T_1 and T_2 relaxation times in the white matter, with a variable degree of involvement of the arcuate U fibers. In Fabry's disease, involvement of the small arteries may cause multifocal small infarcts visible on MRI. The gangliosidosis in addition may show focal decreases of T_2 relaxation time in the thalami, possibly reflecting the calcification seen on CT.^{7,8}

2.2.3 Peroxisomal Disorders

These relate to deficiencies in the activity of respiratory enzymes and organelles of most cells. In most of these diseases, the CNS is involved. Adrenoleukodystrophy has already been discussed above, but there are multiple other rarer diseases that belong to this classification. In general, they produce dysmyelination. Several also show disturbances of neuronal migration. In some, there is an additional inflammatory response.

2.2.4 Mitochondrial Encephalopathies

These group of disorders are characterized by functionally or structurally abnormal mitochondria in the CNS or muscle. They are transmitted by non-Mendelian maternal inheritance, resulting in slowly progressive multisystem diseases with a wide range of clinical presentations, usually appearing in childhood but showing considerable variability depending on their severity.

Imaging is nonspecific.²⁸ There is diffuse but variable white matter atrophy and lengthened T_1 and T_2 signals in the basal ganglia. Focal infarcts may also be seen (Figure 3). Abnormal metabolites, including lactate, have been shown by MRS in the brain lesions. This is thought to be due to impaired aerobic metabolism of pyruvate.^{29,30}

In Leigh's disease, there may be spongy degeneration with astroglial and microglial reaction, with vascular proliferation

Figure 3 Mitochondrial encephalopathy: (a) T_2 -weighted and (b) T_1 -weighted sections in a nine-year-old boy showing increased T_1 and T_2 relaxation times representing focal infarction in the posterior limb of the left internal capsule and thalamus

affecting the basal ganglia, brainstem, and spinal cord. Cerebellar and cerebral white matter undergoes demyelination, with preservation of the nerve cells and axons resulting in hyperintensity and hypointensity on T_2 - and T_1 -weighted images, respectively.

3 DEMYELINATION DISEASE

3.1 Idiopathic

3.1.1 Multiple Sclerosis

Multiple sclerosis (MS) is an idiopathic inflammatory and demyelinating disorder of the central nervous system (CNS). The definitive clinical and pathological features of the disease were established by Charcot³¹ as long ago as 1868. Since then, the disorder's characteristics have been refined, with improvements in imaging giving the most recent insights into its pathophysiology. It is now one of the commonest reasons given for requesting MRI in the northern latitudes of the Western world, and this diagnosis has huge social and economic consequences. It is therefore considered in some depth in the following paragraphs.

Clinically, MS usually follows a fluctuating course, with symptoms varying from paroxysmal and brief to slowly progressive and chronic. The lesions affect single or multiple sites simultaneously, usually involving long white matter tracts, but clinical-pathological correlation is often poor. The disorder leads to visual loss, numbness, tingling in the limbs, spastic weakness, and ataxia.³² Diagnosis is allowed when a combination of signs and symptoms localize lesions in separate and distinct areas of the CNS disseminated in time and space.³³ Supportive laboratory and imaging data can now be defined for research studies, dividing the disease into clinically definite and probable MS, with or without laboratory support.^{34,35}

Although some CT studies using high-dose iodine-enhanced delayed imaging have reported sensitivities as high as 72% when patients are in an acute relapse,³⁶ generally MRI has proved to have considerably greater sensitivity, and, by using intravenous gadolinium-based contrast agents, can separate acute from subacute and chronic lesions.³⁷

Initially, MS lesions were shown at low field on T_1 -weighted (inversion-recovery) sequences,³⁸ but within four years several rigorously controlled studies demonstrated the effectiveness of spin echo sequences where the T_2 -dependent contrast can be organized to maximize the sensitivity between normal and abnormal tissue while minimizing partial volume effects between cerebrospinal fluid (CSF) and adjacent lesions.^{39,40} Although no single sequence will detect all lesions, multifocal supratentorial white matter abnormalities have been shown on moderately T_2 -weighted images in 96.5% of a group of 200 consecutive patients with clinically definite MS.⁴¹ One or more periventricular lesions were seen in 98%, and lesions discrete from the ventricle in 92.5%, with cerebellar lesions in just over half of the group. Normal scans were found in 1.5% of patients. The majority of these lesions were clinically silent; therefore MRI can produce the extra information that helps to fulfill the criteria of dissemination in space (Figure 4). It can also exclude other causes of the patients' signs and symptoms, such as Arnold Chiari malformations and spinocerebellar degeneration. Serial studies with careful repositioning may also

Figure 4 Multiple sclerosis: (a) T_2 -weighted, (b) proton density, and (c) T_1 -weighted sections showing the typical signal changes found in the multiple focal and coalescing acute and chronic plaques

fulfill the criterion of dissemination in time by showing new, often asymptomatic, lesions^{42,43} This high sensitivity has now been confirmed by many workers.^{36,42,44}

The T_1 of apparently normal white matter in patients with MS may be increased,^{42,45} and an apparent increase in the iron content has been found in the thalamus and striatum at high

Table 1 Differential Diagnosis of Multifocal White Matter Lesions

Multiple sclerosis
Aging, small vessel vascular disease, lacunar infarcts
Infarction
Acquired immune deficiency syndrome
Encephalitis (ADEM), (SSPE)
Progressive multifocal leukoencephalopathy
Metastases
Trauma
Radiation damage
Granulomatous disease (e.g., sarcoid)
Inherited white matter disease
Normal (in healthy elderly, especially hypertensive)
Hydrocephalus with CSF interstitial edema

field.⁴⁶ Post-mortem studies have confirmed that the long T_2 lesions found correspond to MS plaques.⁴² This sensitivity makes MRI the most appropriate modality for examining a patient with suspected MS.

Unfortunately, these multifocal white matter lesions may be indistinguishable from other conditions that produce demyelination, gliosis, or periventricular effusions⁴⁷ (Table 1), and between 5 and 30% of apparently normal controls older than 50 years have been shown to have white matter lesions, probably due to asymptomatic cerebrovascular disease. The patient's age and pattern of lesions can help to improve the specificity of the MRI examination.⁴⁸ Fazekas et al.^{49,50} have shown that if at least three areas of increased T_2 signal intensity are present with two of the following features—abutting the body of the lateral ventricles, infratentorial location, and size greater than 5 mm—then the sensitivity is decreased to 88%, but the specificity increases to 96% in patients with clinically definite multiple sclerosis. Although the relaxation times of acute plaques have been found to be longer,⁵¹ the range was wide, and the age of an individual lesion could not be determined by T_1 or T_2 measurement alone. It is important to be able to define new and active lesions to differentiate between multiphasic (MS) and monophasic (ADEM) disease and to determine whether there is evidence of continuing disease progression (e.g., in clinical therapeutic trials).

The areas of perivenular inflammation and edema associated with the acute MS plaque⁵² cause a transient disruption of the blood-brain barrier^{53,54} and allow leakage of intravascular contrast agents. This is shown as enhancement on T_1 -weighted images (Figure 5), and is safer and more effective than high-dose delayed contrast-enhanced CT.⁵³ Correlation with the lesions seen on T_2 -weighted sections is good. Only a small number of cortical or subcortical plaques were seen solely on enhanced T_1 -weighted images. Enhancement is now considered a consistent feature of recognizably new lesions or new parts of existing plaques,⁵⁴ although occasionally blood-brain barrier breakdown develops in older previously nonenhancing plaques associated with no increase in their size. The inflammatory demyelination has been shown pathologically to begin in a perivenular distribution and spread centrifugally, corresponding with the ring enhancement noted in several studies^{37,54} (Figure 5). Gadolinium enhancement is particularly useful in the clear delineation of lesions in the spinal cord and optic nerves, especially if T_1 -weighted fat saturation chemical shift sequences are used to reduce the high signal from surrounding periorbital fat.^{55,56}

Figure 5 Multiple sclerosis: gadolinium-enhanced T_1 -weighted sections showing (a) multiple enhancing acute lesions including a ring enhancing plaque and (b) a nonenhancing chronic cerebellar peduncular lesion

Differences in the enhancement pattern of primary and secondary progressive MS, the two major clinical patient groups, have been identified.⁵⁷ The secondary progressive group had more new lesions (18.2 lesions per patient per year), of which a larger proportion (87%) enhanced. In addition, there was enhancement at the edge of preexisting lesions. This compares with few new lesions (3.3 lesions per patient per year), of which only one enhanced in the primary progressive group at the time when there were no differences over six months in the rates of clinical deterioration between the two groups. This suggests a difference in the underlying dynamics of the inflammatory component of the disease. With improved imaging techniques, e.g., fast scanning methods, and particularly with real-time echo planar imaging,⁵⁸ the complex morphology of the initial phase of gadolinium enhancement after intravenous injection may be further elucidated and related to the lesions on the unenhanced scan. Correlation with lipid imaging may allow study of the relationship between demyelination and inflammation. Advances in the use of MRI and MRS have been reviewed by Paty et al.⁵⁹

Now that new and biologically active lesions can be identified routinely in clinic patients by gadolinium-enhanced T_1 -weighted scans, the association of blood–brain barrier leakage in some but not all of multiple plaques shown on T_2 -weighted images indicates the presence of dissemination in time⁶⁰ and refines the diagnosis of MS. The method can be used to subdivide clinical groups, and will be useful in monitoring and possibly shortening the time required for therapeutic trials (e.g., with steroids⁶¹ and interferon⁶²) in MS.

3.1.2 Schilder's Disease (Myelinoclastic Diffuse Sclerosis)

This is a rare but distinctive acute demyelinating condition, which can be defined by biochemical, pathological, and electrophysiological criteria, yet remains faithful to Schilder's original description of 1912.⁶³ There is a severe selective inflammatory demyelination with sparing of the subcortical U fibers, and extensive attempts at remyelination.

MR white matter changes have been described,⁶⁴ with bilateral involvement of the anterior hemispheres, extensive fluctuating increased relaxation times, mass effect, and varying partial ring enhancement indicating changes in blood–brain barrier breakdown. Other leukodystrophies with a similar appearance such as adrenoleukodystrophy and Pelizaeus–Merzbacher disease must be excluded by biochemical testing.

3.2 Postinflammatory: Viral, Allergic, Immune-mediated Responses to Previous Infection

3.2.1 ADEM

Acute disseminated encephalomyelitis is a demyelinating disease that is thought to be an immune-mediated disorder secondary to a recent viral infection or more rarely to vaccination. It has an acute onset and a monophasic course, in contradistinction to MS. Most patients make a complete recovery, with no neurological sequelae. This makes it one of the most important differential diagnoses in the acute clinical situation.

Pathologically, there is a diffuse perivenous inflammatory process resulting in confluent areas of demyelination. These frequently occur at the corticomedullary junction, with gray matter much less often involved than white. Large areas of

increased T_1 and T_2 relaxation time are found on MRI in both hemispheres, but the effects are usually asymmetrical.⁶⁵ Although in the acute stage, the demyelinating lesions may enhance, the blood–brain barrier quickly returns to normal. As with MS, MRI is much more sensitive than CT at demonstrating these lesions.

3.2.2 SSPE

Subacute sclerosing panencephalitis is a rare progressive demyelination resulting from reactivation of the measles virus due to a defect in immunity that allowed the virus to remain latent.⁶⁶ There is a variable rate of progression, with death between two months and several years after reactivation.

There is perivascular infiltration by inflammatory cells, cortical and subcortical gliosis, and white matter demyelination progressing from occipital to the frontal lobes and from the cerebellum to the brainstem and spinal cord. This is reflected in an increase in T_1 and T_2 relaxation times of the multifocal patchy white matter lesions.^{67,68}

3.2.3 PML

Progressive multifocal leukoencephalopathy is a demyelinating disease probably caused by the papova viruses (e.g., JC and SV40-PML). These are universal childhood infections that are reactivated in the immunosuppressed patient. It is characterized by demyelination, with abnormalities of oligodendrocytes in the white matter. Initially, the lesions are widely disseminated, but later tend to become confluent, producing large lesions. It is now seen with increasing incidence in patients with AIDS⁶⁹ and those treated with immunosuppressive drugs. It most commonly involves the subcortical white matter of the posterior frontal and parietal lobes extending to the level of the trigones and occipital horns of the lateral ventricles (Figure 6). The lesions give an increased T_2 and slightly increased T_1 relaxation time, and because there is only occasional perivascular inflammation in the acute stage, they do not have mass effect and gadolinium enhancement is not usually a feature. These are useful differentiating features from lymphoma and toxoplasmosis.⁷⁰

3.3 Posttherapy

3.3.1 Disseminated Necrotizing Leukoencephalopathy

When patients are treated with intrathecal antineoplastic agents such as methotrexate for disseminated lymphoma, leukemia, or carcinomatosis, a necrotizing leukoencephalopathy can occur despite the fact that the agent does not usually cross the blood–brain barrier.⁷¹ Radiation therapy potentiates this neurotoxicity. There is endothelial injury, loss of oligodendroglial cells, coalescing foci of demyelination, and axonal swelling. The damaged endothelium responds by attempts at repair, resulting in hyalinization, fibrosis, and mineralization of the vessel walls. This causes a relative tissue ischemia, demyelination, and necrosis.

On MRI,⁷² there is a diffuse increase in T_1 and T_2 relaxation times, with no mass effect and little or no gadolinium enhancement, reflecting only the edema and demyelination present.

Figure 6 PML in AIDS: T_2 -weighted images showing (a) extensive subcortical demyelination in the trigonal and occipital regions and, in a different patient, (b) gross loss of white matter substance with periventricular coalescing hyperintensities

The patterns of injury to the white matter from radiation therapy on its own are divided into three stages: (a) acute, (b) early, and (c) delayed. In the first days or weeks after therapy, vasogenic edema may be produced because of transient disruption of the blood-brain barrier, and some enhancement will

occur. In the weeks or months following radiation, demyelination may occur. MRI may show focal or diffuse increases in T_1 and T_2 relaxation times in a patchy often periventricular distribution, which may be asymmetrical, affecting the white matter but generally sparing the corpus callosum, internal capsules, and basal ganglia.^{73,74} The gray matter is only involved in severe cases. Delayed effects can occur months to years after therapeutic irradiation. These are less common, and develop later with hyperfractionated doses. There is endothelial hyperplasia, fibrinoid necrosis of perforating arterioles, and thrombosis. Cerebral necrosis supervenes, with blood-brain barrier disruption, edema, and mass effect. MRI at this stage shows mass effect, increased T_1 and T_2 relaxation times, and enhancement after intravenous gadolinium. Therefore this cannot be differentiated from recurrent tumor with MRI. There is some evidence that measures of the lesion's metabolism with ^{18}F -deoxyglucose positron emission tomography, ^{201}Tl or L-3-[^{123}I]iodo- α -methyltyrosine single photon emission computerized tomography will selectively differentiate the hypometabolic radiation necrosis from the hypermetabolic malignant tumor.^{75,76}

A reversible acute cerebellar and cerebral syndrome has been reported⁷⁷ after systemic high-dose cytarabine therapy used for treatment of postremission and refractory leukemia treatment. Diffuse patchy areas of increased intensity on T_2 -weighted images were shown in the deep white matter of the frontal, occipital, and parietal lobes. Punctate enhancement was observed in the occipital lobes. Over a month, the symptoms and white matter abnormalities resolved. At post-mortem later, there was no evidence of white matter disease.

3.4 Toxic and Degenerative Disease

3.4.1 Central Pontine Myelinolysis

In this condition, there is loss of myelin and oligodendroglia in the central pons, which may extend to the lateral thalamus and mesencephalon, sparing the ventrolateral longitudinal fibers.⁷⁸ It is usually associated with rapidly corrected hyponatremia, often in alcoholics.^{79,80} When there is only a tiny lesion or the patient is in coma due to the underlying disease process, it may be asymptomatic, but usually there is tetraparesis with a pseudobulbar palsy or a 'locked-in' syndrome. Mild cases with full recovery have now been reported.⁸¹

The demyelination is depicted as T_1 and T_2 prolongation with no mass effect, and although there is a single report of ring enhancement, there is usually no blood-brain barrier breakdown.⁸²

3.4.2 Marchiaflava-Bignami Disease

This is characterized by a toxic demyelination of the corpus callosum in alcoholics.^{83,84} A rapidly fatal form and a more chronic form have been recognized. In the acute form, extensive lesions have been reported in the centrum semiovale and corpus callosum, while at the chronic stage only corpus callosum lesions are seen, and occasionally there is a favorable outcome.⁸⁵ MRI shows these as small areas of increased T_1 and T_2 relaxation times, with no mass effect. Enhancement has not been reported.

3.4.3 Carbon Monoxide Encephalopathy

As carbon monoxide binds to the hemoglobin molecule and displaces oxygen, it induces hypoxia and vulnerable cells are destroyed. Although the gray matter structures are damaged first, the white matter is also involved, especially when there is episodic or chronic exposure.

MRI shows areas of increased T_1 and T_2 relaxation time in the thalamus, basal ganglia, hippocampus, and centrum semiovale. These areas may show enhancement with gadolinium in the acute stage. The lesions are usually bilateral and symmetrical, but can be patchy. Laminar necrosis has been reported as high signal cortical foci on T_2 -weighted images.⁸⁶

3.4.4 Substance Abuse

Inhalation of organic solvents and black market drugs such as heroin vapors (pyrolysate) and cocaine produce a wide variety of acute and chronic neurological signs and symptoms. The effects on the white matter will depend largely on the chemical constituent involved.

Xiong et al.⁸⁷ have shown that in toluene (one of the constituents of paint sprays) abuse, there is generalized cerebral, cerebellar, and corpus callosum atrophy, with a loss of gray-white matter contrast associated with diffuse multifocal hyperintensity of the cerebral white matter on T_2 -weighted sequences. Additionally, hypointensity of the thalami are also seen.

Adulterated and synthetically produced drugs can produce severe leukoencephalopathy. Tan et al.⁸⁸ reported on four patients who inhaled contaminated heroin vapor and developed extensive, symmetrical lesions of the white matter of the cerebrum, cerebellum, and midbrain. Selective involvement of the corticospinal tract and lemniscus medialis was also found.

These have to be differentiated from the effects of cocaine abuse, where there is generally neurovascular damage with vasculitis, vasospasm, and thrombosis. Eventually, cerebral atrophy can be seen.⁸⁹

3.4.5 Hypoxic-Ischemic Encephalopathy

This generally refers to brain damage in the fetus and infant. It may be focal or diffuse. When focal, it may be the cause of territorial infarcts such as can occur in cyanotic congenital heart disease when emboli can bypass the filtering effect of the lungs. This will be discussed in Section 3.4.6. In asphyxia, there is diffuse hypoxia hypercarbia, acidosis, and loss of the brain's normal vascular autoregulation, resulting in pressure-passive flow and reduced perfusion. Capillary permeability is also altered. Sudden reperfusion of these weakened capillaries can result in rupture and intracerebral hemorrhage. The periventricular white matter is particularly susceptible, lying at the distal end of the supply zone of the long narrow centripetal arteries that run from the cerebral surface.⁹⁰

When 100 high-risk neonates of different gestational ages were followed prospectively with MRI, CT, and ultrasound examinations,^{91,92} it was found that lesions associated with hypoxic-ischemic encephalopathy such as coagulative necrosis and germinal matrix hemorrhage were best shown on MRI. In the analysis, ultrasound showed 80%, while CT only showed 40% of those lesions depicted on MRI.

This has raised interest in medico-legal circles, since the timing of the insult may be more clearly defined. The appearances of the brain damage on MRI can now give important

clues as to the time and nature of the asphyxia. Barkovich and Truwit⁹³ found that when the asphyxia occurred before the 26th week of gestation, there was dilatation of the ventricles without any signal changes, whereas in older fetuses there was increasing periventricular gliosis. Both periventricular and more peripheral white matter gliosis with associated general atrophy were found in cases who had been partially asphyxiated, or where asphyxia had occurred near term or in postmature fetuses. Total asphyxia involves the deep gray matter nuclei and the brainstem, and presents a different pattern.

These MRI patterns may have prognostic value, with initial studies⁹⁴ reporting good correlations between imaging findings at 8 months and neurodevelopmental outcome at 18 months.

3.4.6 Trauma (Contusions-Shear Injuries)

In children, the effects of asphyxia and mechanical trauma, be they accidental or nonaccidental, may initially produce the same imaging appearance, with generalized cerebral swelling resulting in blurring of the clear distinction between the gray matter and white matter boundaries, ventricular compression, and loss of CSF from the sulci and cisterns. This is due to a combination of edema and a failure of autoregulation producing an increase in cerebral blood volume. This can result in watershed ischemia and infarction, with eventual loss of white matter producing ventricular and sulcal dilatation.

Focal cerebral contusions involve the gyral crests, and can extend into the subcortical and deeper white matter regions, depending on their severity. There is edema and petechial perivascular hemorrhage, but tissue integrity is largely preserved in small lesions. With more severe contusions, the petechial hemorrhages coalesce into focal hematomas, which have some space-occupying effect. These are well shown by MRI at all stages,^{95,96} although, in practice, CT is easier to perform and gives clinically adequate information in the acute stage.

Blunt trauma resulting in sudden acceleration or deceleration of the skull, especially when this is rotational, sets up shear-strain deformation at the moment of impact in response to the inertial differences between tissues of different density and viscosity.⁹⁷ This can cause immediate and irreversible structural damage to axons, and has been termed diffuse axonal injury.⁹⁸⁻¹⁰⁰

Diffuse axonal injury is a pathological diagnosis, and imaging may only show a few apparently focal lesions in the lobar white matter. It is, however, very important to recognize these as the 'hallmark' of associated widespread microscopic axonal disruption. Although CT is the most commonly conducted examination in the acute situation, MRI is much more sensitive^{95,101} and essential when the clinical state is not explained by the CT imaging appearances (Figure 7). In the acute situation, foci of edema that may or may not contain macroscopic hematomas can be seen on T_2 -weighted MRI in the corpus callosum, the parasagittal frontal white matter close to the gray-white matter interface, the basal ganglial regions and the dorso-lateral quadrant of the rostral brainstem.⁹⁶ At the subacute stage, hemorrhage will be better depicted on T_1 -weighted images, but both acutely and in the chronic phase T_2^* gradient echo sequences are most sensitive to deoxyhemoglobin and hemosiderin respectively. MRI can rarely appear entirely normal¹⁰² in severe diffuse axonal injury, and it is only on follow-up that the widespread white matter damage is reflected in atrophy with ventricular and cortical sulcal enlargement.^{100,103,104}

Figure 7 Head injury: T_2^* gradient echo sections in an 25-year-old unconscious patient with a normal CT scan. Multiple focal hypointensities represent hemorrhage at white/gray matter interfaces—evidence of diffuse axonal injury

4 VASCULAR DISEASE

4.1 Infarction

Stroke remains one of the commonest causes of hospital admission in the developed world, has a high morbidity and mortality, and consumes more healthcare resources than any other single disease. Ninety percent of cases are due to ischemia (10% to cerebral hemorrhage) from thrombosis of a nutrient artery, with only a small number due to emboli from the heart or other vessels. Despite treatment advances, the mortality remains at around 50%. It is thought that only preventative public health measures and earlier thrombolytic therapy can improve this situation.¹⁰⁵ This requires the accurate early identification of patients with acute infarcts and those with transient ischemia at risk of completing their infarcts.

Routine unenhanced MRI can detect abnormalities within about 8 h of the onset of symptoms (although changes on MRI with a vessel occlusion stroke model were shown as early as 1–2 h without paramagnetic contrast),^{106,107} whereas CT is normal for at least 14 h and if perfusion is not re-established remains 'bland' for several days. MRI initially shows subtle swelling and an increase in T_1 and T_2 signals due to failure of the 'sodium–potassium' pump and increasing intracellular water–cytotoxic edema. At this stage, function is lost but structure is maintained. It is only with continuing ischemia that blood–brain barrier breakdown occurs, structural integrity is lost, and vasogenic edema supervenes. Although there are anecdotal reports of MRI-defined cytotoxic edema being reversed on treatment of ischemia in humans,^{108,109} and more rigorous demonstrations in cats using diffusion sequences,¹⁰⁷ it has not been established in routine clinical practice whether these MRI changes, unlike those on CT, are reversible.

Recent gadolinium-enhanced MRI studies^{110–112} of the first 24–48 h after the ictus in the clinical population has shed light on this crucially important acute stage. Sato and colleagues¹¹³ studied six patients within 8 h and a further two between 8 and 26 h. They showed areas of cerebral ischemia/infarction using gadolinium-enhanced T_1 -weighted spin echo sequences. Abnormal curvilinear areas of enhancement thought to represent cortical arterial vessels with markedly slowed circulation were seen adjacent to affected brain. This tissue was shown to progress to frank infarction on follow-up CT and MRI. These features have been confirmed and extended by the Iowa group.^{110,114} They demonstrated the vascular flow-related abnormalities with absence of normal flow voids and the presence of arterial enhancement detected within minutes of the onset of symptoms. Brain swelling on T_1 -weighted images without signal changes on T_2 -weighted images was detected within the first few hours. In contrast to the usual absence of parenchymal enhancement typically found in cortical infarctions in the first 24 h, a few lesions showed paradoxical early exaggerated enhancement. These were the transient or partial occlusions and isolated watershed infarcts. Longer term prospective observations through the first fortnight have defined the subacute appearances.¹¹⁵ Three stages have been demonstrated:

- (a) vascular enhancement—days 1–3, seen in 77% of cases;
- (b) leptomeningeal enhancement—days 4–7, seen only in larger infarcts;
- (c) brain parenchymal enhancement—days 7–14, seen in 100% of cases studied.

Enhancement is not noted after two to three months. These changing patterns of enhancement reflect the underlying pathophysiology, and may have prognostic significance; if this proves to be so then gadolinium enhancement will be crucial in the evaluation of early ischemia and its response to intervention.

Once the parenchymal long T_1 and T_2 signal changes are established, the differential diagnosis must be made in a similar way to conventional CT, following consideration of

- (a) the site: vascular territory, watershed region, deep gray or white matter tracts;
- (b) the shape: wedge, involving gray and white matter with subtle bowing of interfaces;
- (c) the margins: sulcal effacement, blurring of the gray and white matter borders;
- (d) the degree of edema;
- (e) the sequence of resolution of mass effect over three to four weeks.¹¹⁶

Hypointensity on heavily T_2 -weighted sequences and the use of gradient echoes or susceptibility mapping can often show petechial hemorrhage in the second week that is not seen on CT. While frank hemorrhage correlates with a worsening clinical state, fine interstitial bleeding mainly due to diapedesis relates neither to anticoagulation nor to a poorer clinical condition.¹¹⁶

The patency of the extracranial and major intracerebral arteries can be assessed on routine MRI sequences as a 'flow void' or with slower laminar flow even as echo rephasing. At present, projectional images produced by time-of-flight and phase contrast angiographic sequences are being evaluated, and may yet replace preoperative conventional cerebral angiography.^{117,118}

Both diffusion imaging^{119,120} and spectroscopy¹²¹ are being used experimentally in clinical populations to try to gain an understanding of microscopic water shifts as the different types of edema develop and to give an insight into the progressive cycles of bioenergetic exchange as oxidative metabolism breaks down in the ischemic brain cells.

4.2 Ischemic White Matter Disease—Normal Aging

Focal and confluent white matter abnormalities seen on MRI do not necessarily represent actual necrosis and infarction, but can be due to a spectrum of chronic cerebrovascular insufficiency.¹²² These merge with the changes found in as many as 30% of the normal aging population over 60 years of age who show no clinical cognitive deficit, but which are seen with increasing frequency in patients with hypertension, diabetes mellitus, and coronary artery disease (Table 1).¹²³

Dilated perivascular spaces give a CSF signal, are usually smaller than lacunar infarcts, and occur in typical locations in the base, deep white matter, and cortex of the brain. Gliosis may become more confluent around these vessels as the vascular insufficiency progresses and produces an increased signal on proton density images in addition to the increased T_2 signal differentiating it from CSF. This has now been confirmed microscopically.

In a small post-mortem study,¹²⁴ histological examination showed that the larger lesions were characterized centrally by necrosis, axonal loss, and demyelination, and therefore represent true infarcts. Reactive astrocytes oriented along the degenerated axons were identified at distances of up to several

centimeters from the central infarct. This isomorphic gliosis shows hyperintensity on T_2 -weighted images, and increases the apparent size of the central lesion. Confirmation has been provided by Munoz et al.,¹²⁵ who investigated the pathological correlates of increased T_2 signal in the centrum ovale in an unselected series of 15 post-mortems. On the basis of size, greater than and less than 10 mm, two types of lesion were described, namely, extensive and punctate. The extensive areas of hyperintensity on T_2 -weighted images were found to show myelin pallor that spared the subcortical U fibers. There was diffuse vacuolation and reduction in glial cell density. The punctate abnormalities were less well defined, and were found to be due to dilated Virchow–Robin spaces.

The white matter changes seen on MRI are therefore non-specific, and although seen with increased frequency in ischemic brains, there is often little or no correlation with the clinical state in the elderly patient.

5 CONCLUSIONS

Over the last 15 years, MRI has become the main diagnostic tool in the investigation of white matter disease. In some conditions, its sensitivity is the key to selecting patients for further attention, while in others it identifies more specific features that in turn lead to further laboratory investigations leading to a final diagnosis. MRI can be used to select patients for treatment and to monitor the effects of this treatment. The implementation of new sequences, faster scanning techniques, and better patient–machine ergonomics will ensure the preeminent position of MRI for the investigation of white matter diseases for the foreseeable future.

Biographical Sketch

Donald M. Hadley. b 1950. M.B.Ch.B., 1974, Ph.D., 1980, D.M.R.D., 1981, Aberdeen University, Scotland; F.R.C.R., 1983, London, UK. Introduced to NMR by Professor John Mallard and Dr Francis Smith while carrying out postdoctoral work in the Department of Bio-medical Physics, University of Aberdeen 1981. MRC research fellow, Glasgow University 1984, consultant and director of Neuroradiology 1992, Institute of Neurological Sciences, Glasgow, UK. Approx. 200 publications. Current research interests: MRI and MRS investigation of acute trauma, epilepsy, metabolic white matter diseases and stroke.

MRI and MRS of Neuropsychiatry

Basant K. Puri

MRC Clinical Sciences Centre, Imperial College School of Medicine, London, UK

1 INTRODUCTION

MRI and MRS studies are becoming increasingly important in neuropsychiatry. In this chapter, the contributions will be considered of such studies to our understanding of schizophrenia, mood disorders, anxiety disorders, obsessive-compulsive disorder, eating disorders, attention deficit hyperactivity disorder (ADHD), psychoactive substance use, Alzheimer's disease, Lewy body disease and Binswanger's disease, Huntington's disease, autism, electroconvulsive therapy, dyslexia, brain changes following incomplete spinal injury in humans, and drug monitoring.

2 SCHIZOPHRENIA

Many studies using MRI have been carried out on patients with schizophrenia since 1983. In a well-researched critical review of these by Chua and McKenna,¹ it was found that the only well-established structural abnormality in schizophrenia is lateral ventricular enlargement; this is modest and overlaps with ventricular size in the normal population. The authors of the review came to the following conclusions: 'there is no consistent evidence from MRI studies for a global reduction in brain size in schizophrenia, and only a minority of studies have pointed to a focal reduction in the size of the frontal lobes. However, the numbers of positive and negative replications are approximately equal for the finding of reduced temporal lobe size, and when the hippocampus and amygdala (and perhaps also the parahippocampal gyrus) are specifically considered this turns into a slight majority in favour of reduced size. A reasonable conclusion might therefore be that, while not yet established beyond reasonable doubt, it is likely that any brain substance abnormality in schizophrenia will be found to be localised to the temporal lobe, where it will be predominantly subcortical and perhaps also predominantly left-sided.'

Recently developed techniques of subvoxel registration of high-resolution three-dimensional (3D) serial MR scans^{2,3} and quantification of changes thereby discovered⁴ have just started to be applied to various aspects of this disorder. For example, when first-episode schizophrenic patients were classified according to Gruzelier's syndromal model,^{5,6} it was found that, compared with normal controls, over an 8-month period patients who were 'withdrawn' showed progressive ventricular enlargement, with an increase in ventricle-to-brain volume ratio. In contrast a group of 'active' patients showed a reduction in ventricle-to-brain volume ratio, with a change that

was opposite in sign and smaller in magnitude.⁷ These findings suggest that opposite patterns of functional hemispheric activation early in the course of schizophrenia may be associated with strikingly different structural cerebral changes. These techniques have also found application in testing specific predictions of Horrobin's neuronal membrane phospholipid model of schizophrenia.^{8,9} In the first example of this, it has been found that in a patient with long-standing disease not being treated with conventional medication, sustained remission of positive and negative symptoms of schizophrenia associated with treatment with the omega-3 fatty acid eicosapentaenoic acid (EPA; Kirunal) was accompanied by a reversal of cerebral atrophy (Figure 1).¹⁰

Using ³¹P MRS to study the prefrontal cortex in schizophrenia, a number of groups, including Pettegrew and colleagues¹¹ and Stanley and colleagues,¹² have reported changes in membrane phospholipid metabolism, irrespective of antipsychotic medication status, with reduced levels of phosphomonoesters (precursors of phospholipid biosynthesis) and increased levels of both phosphodiesteres (phospholipid breakdown products) and intracellular magnesium ions. It has been suggested that these findings may be fundamentally related to the pathophysiology of schizophrenia,¹¹⁻¹³ with the reduced levels of phosphomonoesters being caused by reduced biosynthesis or altered degradation and the elevated levels of phosphodiesteres being associated with increased activity of phospholipase A₂ or A₁, or perhaps decreased phosphodiesterase activity. An alternative explanation involves a putative disturbance of metabolic compartmentation of phosphatidylcholine biosynthesis.¹⁴

Many studies using proton MRS have demonstrated a reduction in the neuronal marker *N*-acetylaspartate, particularly in the left temporal lobe. In a recent study combining this technique with MRI, the volume of cortical gray matter was found to be reduced in patients with schizophrenia, while the *N*-acetylaspartate signal intensity from a comparable region was normal; by comparison, the volume of cortical white matter was normal while the *N*-acetylaspartate signal intensity from a comparable region was reduced.¹⁵ The lack of reduction in gray matter *N*-acetylaspartate signal intensity suggests that the cortical gray matter deficit involved both neuronal and glial compartments, rather than a neurodegenerative process in which there is a decrease in the neuronal relative to the glial compartment. The reduced white matter *N*-acetylaspartate signal intensity without a white matter volume deficit may reflect abnormal axonal connections.¹⁵

3 MOOD DISORDERS

To date there have been relatively few MR studies of mood disorders and the findings are not consistent. For example, ventricular enlargement is an inconsistent finding in depression (using MRI or computed tomography (CT)); when it has been found it has sometimes been shown to be positively correlated with the length of illness. Neither first-episode bipolar disorder nor first-episode major depression appear to be associated with ventricular enlargement, however.¹⁶ Another inconsistent finding is the possibility of an increased frequency of signal hyperintensities on *T*₂-weighted scans in elderly depressed patients, which may be associated with poor cognitive perform-

Figure 1 MRI in a patient with long-term schizophrenia. (a) Transverse image of the brain 12 months prior to commencing treatment with eicosapentaenoic acid (EPA). (b) Transverse image of the brain at baseline (0 months) with respect to EPA treatment. (c) Registered difference image of the baseline scan minus the scan at -12 months ((b) minus (a)). The dark lines around the ventricles are caused by a decrease in brain size. (d) Registered difference image of the scan at 6 months minus the scan at baseline (0 months). The white lines around the ventricles are caused by an increase in brain size. Changes are also seen in the cerebral cortex, with narrowing evident in some sulci and increased volume evident in some gyri

ance.^{17,18} Although such hyperintensities may be a marker of underlying pathology, they are by no means specific to depression and indeed may also occur in older normal controls. It has been reported that the presence of such hyperintensities in both the basal ganglia and the pontine reticular formation in patients aged 65 years and over is associated with a poor response to antidepressant monotherapy.¹⁹ It has also been suggested that treatment-resistant chronic unipolar depression is associated with reduced gray matter density in the left temporal cortex, including the hippocampus.²⁰ Studies using ³¹P MRS and ¹H MRS have indicated possible abnormalities in membrane phospholipid metabolism, high-energy phosphate metabolism, and intracellular pH in mood disorders.²¹

4 ANXIETY DISORDERS

There have been very few MR studies of anxiety disorders, perhaps because anxiety and claustrophobic symptoms constitute a recognized cause of incomplete or cancelled MR examinations.²² In one ³¹P MRS study of the frontal lobes in panic disorder, no significant differences were found between patients and controls in ³¹P metabolite levels, although a significant asymmetry (left greater than right) of phosphocreatine concentration was found in the patients; raised intracellular pH in 2 out of 18 of the patients may have resulted from respiratory alkalosis secondary to hyperventilation in the anxiety state.²³

5 OBSESSIVE-COMPULSIVE DISORDER

Structural neuroimaging studies indicate that at least a subgroup of patients with obsessive-compulsive disorder may have abnormal basal ganglia development.²⁴ Although not all such studies demonstrate reduced volumes of these structures, it is noteworthy that a reduced level of the neuronal marker *N*-acetylaspartate has been found in either the left²⁵ or right²⁶ corpus striatum in obsessive-compulsive disorder using proton MRS, even when volumetric MRI studies of the same patients do not show reduced volumes.²⁵ Hence the inconsistent volumetric findings may reflect the relatively poorer sensitivity of MRI morphometry for detecting neuronal loss compared with proton MRS measurement of *N*-acetylaspartate.

6 EATING DISORDERS

The CT finding of cerebral atrophy in patients with eating disorders has been replicated using MRI.^{27,28} Female patients with anorexia nervosa and bulimia nervosa have been reported to have smaller pituitary glands than matched controls.^{29,30} In the absence of any other pituitary pathology, this atrophy is likely to be secondary to nutritional or endocrine alterations. Other reported structural abnormalities include enlarged lateral ventricles with dilated cortical and cerebellar sulci,³¹ and subcortical signal hyperintensities on *T*₂-weighted scans.³²

In a small cerebral ³¹P MRS study of anorexia nervosa before treatment, increased levels of phosphodiesterases were found compared with controls, while decreased phosphomonoesters were found that were associated with malnutrition

reflected by endocrinological abnormalities.³³ These data suggest that severe malnutrition in patients with anorexia nervosa may result in an abnormality in membrane phospholipid metabolism, which might be related etiologically to the cerebral atrophy of anorexia nervosa. In another study of patients with anorexia nervosa recording proton MR spectra from parieto-occipital white matter immediately following an interval of excessive loss of body mass, higher signal intensity ratios of choline-containing compounds relative to total creatine and lower ratios of *N*-acetylaspartate relative to choline-containing compounds were found compared with controls,³⁴ suggesting that starvation may be associated with an abnormal neuronal membrane turnover in the white matter of the brain.

7 ATTENTION DEFICIT HYPERACTIVITY DISORDER

Recent MRI studies have shown that some regions of the frontal lobes (anterior superior and inferior) and basal ganglia (caudate nucleus and globus pallidus) are about 10% smaller in ADHD groups than in control groups of children,³⁵ with the right caudate nucleus being larger,³⁶ or left caudate being smaller,³⁷ in children with ADHD. These findings are consistent with theories implicating frontal-striatal circuit abnormalities in this disorder. Also in harmony with this theory is the fact that the corpus callosum has been found relatively consistently to be smaller in children with ADHD, particularly in the region of the genu and splenium.³⁸ Recently, the cerebellum has been systematically studied in this disorder; the vermal volume was found to be significantly smaller in a large sample of boys with ADHD than in matched controls.³⁹ This reduction involved mainly the posterior inferior lobe (lobules VIII to X) but not the posterior superior lobe (lobules VI to VII) and suggests that perhaps cerebello-thalamo-prefrontal circuit dysfunction may subserve the motor control, inhibition, and executive function deficits seen in this disorder.

Advances in genetic studies of ADHD have occurred while these advances in structural neuroimaging have been taking place. An important example of how both of these investigative techniques can complement each other relates to polymorphisms of the D₄ dopamine receptor (*DRD4*). One allele with seven tandem repeats in exon 3 (*DRD4*7R*) has been associated with ADHD, and when this putative association was investigated by Castellanos and colleagues, it was found that cerebral MRI measures, previously found to discriminate ADHD patients from controls, did not differ significantly between subjects having and those lacking a *DRD4*7R* allele.⁴⁰ Hence the MRI results did not support the reported association between *DRD4*7R* and the behavioral or brain morphometric phenotype associated with ADHD.

8 PSYCHOACTIVE SUBSTANCE ABUSE

Chronic alcoholism is associated with MRI-detectable atrophic changes in many regions of the brain, including the cerebral cortex, cerebellum,⁴¹ and corpus callosum.⁴² Hippocampal volume reduction is proportional to the reduction in volume of the brain as a whole.⁴³ It has been found that over a 5-year period brain volume shrinkage is exaggerated in the pre-

frontal cortex in normal aging but with additional loss occurring in the anterior superior temporal cortex in alcoholism.⁴⁴ This association of cortical gray matter volume reduction with alcohol consumption over time suggests that continued alcohol abuse results in progressive cerebral tissue volume shrinkage.

MRI, but not CT, has been shown to be useful in confirming the diagnosis of acute Wernicke's encephalopathy. In one recent study, increased T_2 signal of the paraventricular regions of the thalamus and the mesencephalic periaqueductal regions was observed in patients with Wernicke's encephalopathy compared with both controls and asymptomatic chronic alcohol abusers, with the sensitivity of MRI in revealing evidence of this disease being 53% and the specificity 93%.⁴⁵ It should be borne in mind, however, that the absence of abnormalities on MRI does not exclude this diagnosis.

With MRI, widespread cerebral atrophy is seen in alcoholic Korsakoff patients;⁴⁶ this is largely subcortical and does not develop independently of the diencephalic pathology. It should be noted that while chronic alcohol abuse is associated with mammillary body and cerebellar tissue volume loss, these markers do not distinguish accurately between amnesic and nonamnesic patients; mammillary body atrophy that is detectable on MRI is not necessary for the development of amnesia in alcoholic patients.⁴⁷

It has recently been shown that cerebral MRI may be of use clinically in the differential diagnosis of chronic alcohol abuse and schizophrenia.⁴⁸ In this study, patients with both disorders showed widespread cortical gray matter volume deficits compared with controls, but only those with chronic alcoholism showed white matter volume deficits. The patients with schizophrenia had significantly greater volume deficits in prefrontal and anterior superior temporal gray matter than in more posterior cortical regions. By contrast, the deficits in the patients with alcoholism were relatively homogeneous across the cortex. For white matter, the deficits in the patients with alcoholism were greatest in the prefrontal and temporoparietal regions. Although both patient groups had abnormally larger cortical sulci and lateral and third ventricles than the controls, the patients with alcoholism had significantly larger sulcal volumes in the frontal, anterior, and posterior parieto-occipital regions than those with schizophrenia.

Reduced levels of *N*-acetylaspartate and choline have been found using cerebral proton MRS in chronic alcoholism.⁴⁹ The reduction of *N*-acetylaspartate is consistent with neuronal loss while the reduction in choline may be related to neuronal membrane lipid changes.

In a recent large MRI and proton MRS study comparing asymptomatic abstinent cocaine users with matched controls, it was found that while the ventricle-to-brain ratio and level of white matter lesions did not differ significantly between the two groups, elevated creatine and *myo*-inositol in the white matter were associated with cocaine use.⁵⁰ The *N*-acetylaspartate level was normal in the cocaine users, suggesting that there was no neuronal loss or damage in the brain regions examined. It was, therefore, concluded that the neurochemical abnormalities observed might result from alterations in non-neuronal brain tissue.

MRI changes associated with chronic toluene abuse include cerebral atrophy, cerebral and cerebellar white matter T_2 hyperintensity, T_2 hyperintensity involving the middle cerebellar peduncle and the posterior limb of the internal capsule, and T_2

hypointensity involving the basal ganglia and thalamus.^{51,52} Chronic solvent abusers who have white matter MRI changes have been found to have a lower performance intelligence quotient, as measured by the Weschler Adult Intelligence Scale – Revised, with a particularly low score on the digit symbol subtest.⁵³

In polysubstance abusers, there is MRI evidence of reduced volume of the prefrontal cortex (both left and right) consistent with either atrophy or hypoplasia.⁵⁴ Ventriculomegaly has not been found to be a feature.⁵⁵ Abnormal cerebral metabolism has been found using ^{31}P MRS in male polysubstance abusers during early withdrawal: increased phosphomonoesters and decreased β -nucleotide triphosphates were found in the abusers compared with controls, indicating that cerebral high-energy phosphate and phospholipid metabolite changes result from long-term drug abuse and/or withdrawal.⁵⁶

9 ALZHEIMER'S DISEASE, LEWY BODY DISEASE, AND BINSWANGER'S DISEASE

The first part of this section considers recent studies focusing on the use of MRI in differentiating Alzheimer's disease from both normal aging and other causes of dementia.

While the finding of cortical or subcortical atrophy on MRI or CT is not pathognomonic of Alzheimer's disease, hippocampal atrophy provides a useful early marker of the disorder, although further longitudinal and neuropathological study is required.⁵⁷ CT- and MRI-based measurements of hippocampal atrophy may provide useful diagnostic information for differentiating patients with probable Alzheimer's disease from normal elderly individuals.

A recent pilot study has indicated that MRI may have a role in assisting with the clinical differentiation between dementia with Lewy bodies and Alzheimer's disease.⁵⁸ Subjects with known or probable Alzheimer's disease were found to have significantly smaller left temporal lobes and parahippocampal gyri than those with known or probable Lewy body disease. Medial temporal atrophy was present in 9 out of 11 patients with Alzheimer's disease and absent in six out of nine patients with Lewy body disease. While two patients with neuropathologically confirmed Lewy body disease had severe medial temporal atrophy, in both concurrent Alzheimer's disease-type pathology was present in the temporal lobe. Therefore, this pilot study supports the hypothesis that a greater burden of pathology centers on the temporal lobes in Alzheimer's disease compared with Lewy body disease, unless Lewy body disease occurs with concurrent Alzheimer pathology.

Another recent study has suggested that diffusion-weighted MRI may be useful in the differential diagnosis of subcortical arteriosclerotic encephalopathy (vascular dementia of the Binswanger type) and Alzheimer's disease with white matter lesions.⁵⁹ Apparent diffusion coefficients in the anterior and posterior white matter and the genu and splenium of the corpus callosum were significantly higher in patients with both these disorders compared with age-matched controls, with apparent diffusion coefficient values in the groups with Binswanger's disease and those with Alzheimer's disease being almost the same. Apparent diffusion coefficient ratios, defined as diffusion-restricted perpendicular to the direction of nerve fibers, were also significantly higher in both groups of patients than in the

controls. However, there were regional differences in these ratios in the two disorders, with ratios in Binswanger's disease being higher in the anterior portions of the white matter while ratios in Alzheimer's disease were higher in the posterior portions.

In vitro and in vivo ^{31}P MRS studies of the brain in Alzheimer's disease show alterations in membrane phospholipid metabolism and high-energy phosphate metabolism: compared with control subjects, mildly demented patients with Alzheimer's disease have increased levels of phosphomonoesters, decreased levels of phosphocreatine and probably adenosine diphosphate, and an increased oxidative metabolic rate; as the dementia worsens, levels of phosphomonoesters decrease and levels of phosphocreatine and adenosine diphosphate increase.⁶⁰ The changes in oxidative metabolic rate suggest that the brain in Alzheimer's disease is under energetic stress while the phosphomonoester findings implicate basic defects in membrane metabolism in the brain.⁶⁰ Thus, in addition to aiding with diagnosis, ^{31}P MRS may provide a noninvasive tool to follow both the progression of this disorder and any response to putative therapeutic interventions.

Proton MRS studies of occipital gray matter show that reduced levels of *N*-acetylaspartate (presumably reflecting neuronal loss) and increased levels of *myo*-inositol characterize Alzheimer's disease.^{61,62} Studies using proton MRS to measure cerebral amino acids have tended to demonstrate increased glutamate levels and sometimes reduced γ -aminobutyric acid (GABA); following neuronal loss, the remaining neurons might be exposed to excess glutamate and relatively low levels of GABA, an imbalance that might be neurotoxic.^{63,64}

10 HUNTINGTON'S DISEASE

Initially, structural neuroimaging studies showed atrophy of the caudate and loss of definition between the caudate and the adjacent ventricle as Huntington's disease progresses; however more recent studies have also shown cortical atrophy, particularly in the frontal lobes.⁶⁵

Using proton MRS, Jenkins and colleagues found that lactate concentrations were increased in the occipital cortex of patients with symptomatic Huntington's disease compared with normal controls, with the lactate level correlating with duration of illness.⁶⁶ Several patients in the same study also showed highly elevated lactate levels in the basal ganglia, while basal ganglia levels of *N*-acetylaspartate were lowered and choline dramatically elevated, relative to creatine, reflecting neuronal loss and gliosis in this brain region. The authors of this study suggested that these findings are consistent with a possible defect in energy metabolism in Huntington's disease, which could contribute to the pathogenesis of the disease, and that the presence of elevated lactate might provide a simple marker that could be followed over time noninvasively and repeatedly to aid in devising and monitoring possible therapies.

A more recent proton MRS study by Taylor-Robinson and colleagues found an elevated ratio of glutamine and glutamate relative to creatine in the striatum compared with healthy controls, suggesting disordered striatal glutamate metabolism and possibly supporting the theory of glutamate excitotoxicity in Huntington's disease.⁶⁷

Huntington's disease is now known to result from expanded CAG repeats in a gene on chromosome 4, a possible consequence of which might be progressive impairment of energy metabolism. Jenkins and colleagues have recently extended their previous studies to examine correlations between proton MRS changes and CAG repeat number.⁶⁸ The spectra in three presymptomatic gene-positive patients were found to be identical to normal control subjects in cortical regions, but three in eight showed elevated lactate in the striatum. Similar to recently reported increases in task-related activation of the striatum in the dominant hemisphere, they found that striatal lactate levels in patients with Huntington's disease were markedly asymmetric (left greater than right). Markers of neuronal degeneration, decreased *N*-acetylaspartate to creatine and increased choline to creatine ratios, were symmetric. Both decreased *N*-acetylaspartate and increased lactate in the striatum significantly correlated with duration of symptoms. When divided by the patient's age, an individual's striatal *N*-acetylaspartate loss and lactate increase were found to correlate with the subject's CAG repeat number, with correlation coefficients of 0.8 and 0.7, respectively. Similar correlations were noted between postmortem cell loss and age versus CAG repeat length. Together, these data provide further evidence for an interaction between neuronal activation and a defect in energy metabolism in Huntington's disease that may extend to presymptomatic subjects.⁶⁸

11 AUTISM

MRI studies of individuals with autism have variously and inconsistently shown evidence of hypoplasia of the cerebellum and brainstem with increased size of the fourth ventricle, increased brain volume (though with relative hypofrontality), and smaller size of the body and posterior subregions of the corpus callosum; in addition, previous pneumoencephalographic and CT studies have described lateral ventricular enlargement while MRI studies in general have failed to show abnormality in limbic structures.⁶⁹ The degree of cerebellar hypoplasia is significantly correlated with the degree of slowed attentional orienting to visual cues in both children and adults with autism.⁷⁰ It should be noted that even in the absence of abnormal MRI findings, autism may be associated with focal areas of decreased perfusion.⁷¹

The finding that autism is not necessarily associated with MRI abnormalities is consistent with the results of a recent cerebral proton MRS study comparing 28 patients with autism with both 28 age-matched patients with unclassified mental retardation and 25 age-matched healthy children. The ratio of *N*-acetylaspartate to choline was lower in the nonautistic patients with mental retardation than in the patients with autism and the controls, and, interestingly, there were no significant differences in this ratio between patients with autism and controls.⁷²

A ^{31}P MRS study of the dorsal prefrontal cortex of 11 high-functioning autistic adolescent and young adult men and 11 matched normal controls found that the autistic group had decreased levels of phosphocreatine, α -ATP, α -ADP, dinucleotides, and diphosphosugars compared with the controls.⁷³ When the metabolite levels were compared within each subject group with psychological and language test scores, a common pattern of correlations was observed across measures in the

Figure 2 MRI in patients receiving electroconvulsive therapy. (a) Transverse T_1 -weighted MR baseline scan showing the anatomy. (b) Difference image obtained by subtracting the baseline scan from the registered follow-up scan showing no evidence of acute structural changes in the brain following electroconvulsive therapy

autistic group, but not in the control group. As test performance declined in the autistic subjects, levels of the most labile high-energy phosphate compound and of membrane-building blocks decreased, and levels of membrane breakdown products increased. No significant correlations were present with age in either group or with IQ in the control group, suggesting that these findings were not the consequence of age or IQ effects. This study provides some evidence of alterations in brain energy and phospholipid metabolism in autism that correlate with psychological and language deficits.

12 ELECTROCONVULSIVE THERAPY

For many years clinicians have been concerned that electroconvulsive therapy may result in acute cerebral structural changes. Indeed, some retrospective imaging studies using MRI and CT have reported an association between a history of electroconvulsive therapy and cerebral change, particularly affecting the lateral ventricles and/or cerebral cortex. However, recently, a prospective MRI study of four electroconvulsive therapy-naïve depressed patients in which they underwent scanning 1 week prior to their first treatment with electroconvulsive therapy and then again following this treatment showed that, using accurate subvoxel registration and subtraction of serial MR images,^{2,3} there was no significant difference in cerebral structure following electroconvulsive therapy, either within 24 h or after 6 weeks (Figure 2).⁷⁴

A proton and ^{31}P MRS study of three patients found no evidence of changes in lactate or in cerebral energy metabolism following electroconvulsive therapy.⁷⁵ However, Woods and Chiu have found, using proton MRS, that electroconvulsive therapy reliably induces an elevation in the lipid signal that resonates at approximately 1.2 ppm and observed a similar increase in brain lipids in a patient with temporal lobe epilepsy temporarily off medication, the signal disappearing following restarting medication.⁷⁶ This is of interest given that elevations of brain concentrations of arachidonic acid and other free fatty acids have been demonstrated to occur after seizures induced in animals. Large shifts of potassium ions from the intra- to the extracellular space occur during seizure activity, and free fatty acids have a direct effect on membrane potassium ion conductance, suggesting that free fatty acids may play a primary role in seizure evolution in brain tissue.⁷⁶

13 DYSLEXIA

MRI studies have inconsistently shown reversed or diminished asymmetry, compared with normal, in the brain in children with dyslexia, including loss of the usual left greater than right asymmetry of the lateral ventricles and right greater than left asymmetry of the temporal lobes; loss of the normal left greater than right asymmetry of the planum temporale in adolescents, which correlates with the degree of phonological decoding deficits; reversal of the normal left greater than right asymmetry of the angular gyrus in familial dyslexia; and loss

Figure 3 Volume changes in lateral ventricles following oral glucose loading. Blood glucose concentrations (○) and lateral ventricular volumes (●) for two human subjects (a and b) who each ingested 53.7 g glucose at time zero. (After Puri et al.⁸⁵)

of normal right greater than left asymmetry of the frontal cortices and bilaterally smaller size of the frontal cortices. Inconsistent corpus callosum changes have also been reported.⁷⁷

In the first ³¹P MRS study of dyslexia, Richardson and colleagues found elevated phosphomonoesters in the brain in dyslexia compared with that in controls.⁷⁸ This finding is consistent with the hypothesis that neuronal membrane phospholipid metabolism is abnormal in dyslexia, with reduced incorporation of phospholipids into neuronal membranes occurring.⁷⁹

The first proton MRS study of dyslexia showed lateral differences in the ratios of choline to *N*-acetylaspartate and of creatine to *N*-acetylaspartate in the temporo-parietal region and the cerebellum in dyslexic subjects but not in controls.⁸⁰

14 SPINAL INJURY

The first proton MRS study of the human motor cortex following incomplete spinal cord injury showed elevation of *N*-acetylaspartate in this part of the brain compared with normal controls.⁸¹ The authors suggested that this might reflect neuronal adaptation to injury, the finding being consistent with the hypothesis that dendritic sprouting occurs in the motor cortex following recovery from incomplete spinal injury in humans.

Clinically, this finding also suggests that MRS might provide a noninvasive method for monitoring such patients.

15 DRUG MONITORING

It is possible to use ⁷Li MRS directly to measure the cerebral concentration of lithium while ¹⁹F MRS can be used to measure the cerebral concentrations of psychotropic drugs containing fluorine, for example the selective serotonin reuptake inhibitor fluoxetine and the antipsychotics trifluoperazine and fluphenazine.⁸²

16 FUTURE DIRECTIONS

As mentioned above, the recently developed MRI techniques of subvoxel registration of high-resolution 3D serial MR scans^{2,3} and quantification of the changes thereby discovered⁴ are only just starting to be applied in neuroimaging studies. The sensitivity and accuracy of these techniques hold great promise for neuroimaging applications and the discovery of important new facts concerning the central nervous system.^{83,84} For example, they have been used recently to show that volumetric change takes place in the lateral ventricles in the human brain following oral glucose loading (Figure 3).⁸⁵

Cerebral MRS is currently used primarily as a research tool in neuropsychiatry; in due course it is likely to become more widely used diagnostically and prognostically.

It seems probable that MRI and MRS will interface more often with other disciplines (for instance molecular genetics, as in ADHD) and other investigative tools (such as transcranial magnetic stimulation).

In summary, MRI and MRS are proving to be extremely useful in neuroscientific and neuropsychiatric research. These powerful noninvasive tools are likely to continue to grow in importance in these fields and to gain ever more important clinical applications.

Pediatric Brain MRI: Applications in Neonates and Infants

Jacqueline M. Pennock

Royal Postgraduate Medical School, Hammersmith Hospital, London, UK

1 INTRODUCTION

The ability of magnetic resonance imaging (MRI) to provide physiological, anatomical and functional information without posing any biological hazard makes it particularly suitable for studying the central nervous system of children where repeated examinations may be critical for diagnosis.

Clinical MRI systems are almost always designed for adults and sequences are optimized to maximize contrast in adults. The first task in examining infants is often to modify the equipment to optimize it for small infants and to develop imaging patterns which provide equivalent contrast to that seen in adults. This article covers particular techniques used to examine preterm babies and infants, the normal appearances of the developing brain, and clinical conditions encountered in infants and children.

2 PATIENT PREPARATION

For a successful examination, both the child and the parent must be considered. We actively encourage parents to accompany their infants to the imaging unit so that they do not feel excluded and can see that their child is asleep and comfortable. If it is their wish, we invite the parents to watch us putting their baby into the machine, bearing in mind that for many parents seeing their sleeping child enclosed in a head coil and being slid into the machine may be a stressful experience. With older children, parents are asked to stay with them during the examination, although talking is limited to the time between scans.

2.1 Sedation

Diagnostic images can only be obtained in a quiet, immobile child, so if possible appointments are made to coincide with the natural sleeping pattern of the child. Children come to a children's day ward where they are seen by a pediatrician who goes through the metal check with the parent and ensures that there are no contraindications to sedation. This is given to children under 2 years of age 20–30 min before the scan time. The child stays on the ward with the supervision of a nurse until she or he is asleep and is then brought to the scanning unit. Once the scan is over, the child returns to the ward until she or he is fully recovered.

Preterm infants and neonates are fed prior to the examination and scanned during natural sleep. However, in the irritable stable neonate, oral chloral hydrate via a nasal gastric tube or per rectum (50–80 mg kg⁻¹) is used. For infants aged 6 weeks and over, oral chloral hydrate (70–100 mg kg⁻¹) is given. This dose is successful in most children up to the age of 3 years or about 15 kg. Once the child is asleep, further immobilization is achieved by partly surrounding the head with a plastic globe filled with tiny polystyrene balls which is then evacuated. This minimizes motion, helps to keep the baby warm and provides insulation from sound. Swaddling the infant also prevents movement and provides extra security and warmth. Neonates usually sleep better on their sides, and this position also reduces the risk of inhalation of regurgitated milk or vomit.

MRI of the critically ill intubated infant is feasible as long as the imaging unit has the appropriate facilities to offer the same care for the child as does the neonatal intensive care unit (NICU). These include suitably trained staff, gases and suction, and pediatric-sized resuscitation equipment.

In our hospital the baby is brought from the NICU in a standard Vickers transport incubator. The incubator is parked and locked in a corner of the room well beyond the 5 G (5×10^{-4} T) line and, as an extra precaution, attached to a wall by a plastic chain. Infants are ventilated from the Vicker nevent unit via long extension tubes from the incubator to the baby, with appropriate adjustment of the inspiratory and expiratory pressure to take account of the large dead space.

2.2 Monitoring

Monitoring of the sedated and naturally sleeping infant is mandatory. A variety of magnetic resonance (MR) compatible physiological monitoring devices is available for monitoring blood pressure, heart rate, respiration, and blood oxygen saturation. We use electrocardiogram (ECG) monitoring with fiber optic leads and infant-sized MR-compatible electrodes, as well as pulse oximetry with neonatal probes attached to the infant's foot to display blood oxygen saturation and pulse rate. Further details and information on the sedation and anesthesia of the critically ill infant is available in the radiological literature.^{1–3}

2.3 General Safety

Baby clothing with metal poppers should be removed. Although the fastenings are not ferromagnetic they may conduct eddy currents which can lead to artifacted images. An infant is almost always accompanied by medical staff and parents unaccustomed to an MR unit, and constant care has to be taken to check for loose metal objects on persons in a magnetic field. Pacemakers and aneurysm clips are usually associated with an older population; however, young mothers may also have aneurysm clips. A strict routine and protocol for access is necessary.

Scheduling of sedated infants and sleeping children is difficult and requires considerable flexibility. It is much easier to have exclusively pediatric sessions and not to try to mix sedated and sleeping children with ambulant adults. Prior knowledge of the clinical condition with a presumptive diagnosis is essential so that suitable protocols can be set up before each scan. Protocols which we have found useful in neonatal imaging are given in Table 1.

Table 1 Suggested Protocol for Imaging Neonates at 1.0 T

	First scan (all ages, short <i>TR/TE</i> SE)	Inversion recovery	<i>T</i> ₂ -weighted spin echo
Slice orientation	Transverse	Transverse	Transverse
Phase-encoding axis	Left–right	Left–right	Left–right
Number of slices	24	18	24
Echo time (<i>TE</i>)	20	30	200–120 ^a
Inversion time (<i>TI</i>)	–	1500–700 ^a	–
Repeat time (<i>TR</i>)	860	6000–3500	3500
Field-of-view	22–25	22–25 ^a	22–25
Phase resolution	192	128	128
Frequency encode resolution	256	256	256
Number of signals (average)	2	1 or 2	1 or 2
Slice thickness (mm)	4	5–6	5
Slice gap	0	0	0
Receive coil	Small diameter	Small diameter	Small diameter
Flip angle (degrees)	90	90	90
Estimated time of scan	4 min	Variable	Variable

^aChoice will depend on age of infant (see Table 2).

3 TECHNICAL CONSIDERATIONS

The signal-to-noise ratio is an important factor in producing high quality diagnostic images at all field strengths. Image quality can be improved by using the smallest diameter coil available. Adult knee coils with an internal diameter of approximately 19 cm have proved useful for imaging premature infants (head circumference approximately 30 cm) as well as infants up to 45 weeks gestational age. For children up to 18 months of age we use a receiver coil with an internal diameter of 24 cm. This coil is made in two halves of clear Perspex, making positioning and observation of the baby easier.

4 PULSE SEQUENCES

The neonatal brain contains a higher proportion of water (92–95%) than the adult brain (82–85%) and this is associated with a marked increase in *T*₁ and *T*₂.⁴ The amount of water in

the brain falls with increasing age, and by 2 years of age it has almost reached adult levels.⁵

A brief description of the standard pulse sequences and useful variations for imaging neonates and children are given below. The major pulse sequences and their specific variations for neonatal practice are shown in Table 2.

4.1 The Inversion–Recovery (IR) Sequence

The short inversion time (*TI*) inversion–recovery (STIR) sequence is of value in demonstrating myelination and pathological periventricular changes where the cerebrospinal fluid (CSF) signal can be kept less than that of brain.⁶ This sequence has many features in common with the *T*₂-weighted spin echo sequence, but gives greater gray–white matter contrast (Figure 1).

The medium *TI* version of the IR sequence provides excellent gray–white matter contrast and displays white matter with high signal intensity and gray matter with a lower signal intensity. This sequence is particularly useful for scan-

Table 2 Inversion Recovery and Spin Echo (SE) sequences at 1.0 T

Age	Type	<i>TR</i> (ms)	<i>TE</i> (ms)	<i>TI</i> (ms)
<i>Inversion–recovery sequences</i>				
29–34 weeks	IR medium <i>TI</i>	7000	30	1500
35–39 weeks		6500	30	1200
40 weeks to 3 months		3800	30	950
>3 months to 2 years		3500	30	800
>2 years		3200	30	700
<3 months	FLAIR long <i>TI</i>	6000	240	2100
>3 months		6000	160	2100
All ages	STIR short <i>TI</i>	3800	30	130–150
<i>Spin echo sequences</i>				
All ages	<i>T</i> ₁ -weighted	860	20	
≤2 years	<i>T</i> ₂ -weighted	3500	120	
>2 years	<i>T</i> ₂ -weighted	2500	20/80	

Figure 1 Female infant aged 9 months. Short TI inversion recovery (STIR) sequence (IR 3000/30/125). Pathological white matter adjacent to the posterior horns of the lateral ventricles is seen (arrows). The CSF is displayed as moderate signal intensity and the myelin as low signal intensity

ning the developing brain, especially for assessment of myelination, but the TI requires adjustment to accommodate the changing water content of the brain with age (see Figure 4 and Section 5).

The long TI , long TE version of this sequence is designed to display the CSF with low signal intensity and heavy T_2 -weighting. The acronym for this sequence is FLAIR (fluid attenuated inversion-recovery sequence) and it provides better lesion conspicuity than conventional T_2 spin echo sequences (Figure 2).⁷ It is not always helpful in the immature brain, but in older children we have found it of great help for lesions with a periventricular distribution.

4.2 The Spin Echo Sequence

The short TR TE T_1 -weighted spin echo sequence has less gray-white matter contrast than the medium TI inversion recovery sequence. However, the former sequence is quicker and is recommended for use as the first sequence in all studies on sedated infants under 2 years of age. It is extremely useful for the assessment of brain swelling, hemorrhage, cystic change, and contrast enhancement with gadopentetate dimeglumine.

With the T_2 -weighted spin echo sequence it is necessary to increase the TE to 120–200 ms in order to identify long T_2 lesions against the background of the long T_2 of the immature brain.⁸ However, the extended TE results in high signal inten-

Figure 2 Male infant aged 1 year. (a) T_2 -weighted spin echo (SE 2700/120) and (b) FLAIR (IR 7203/240/2100) sequences. A porencephalic cyst is seen in both images in the left hemisphere. Gliosis is shown as high signal intensity in both sequences; however, it appears more extensive and is seen with greater conspicuity in (b) (arrows). Note the low signal intensity of CSF within the porencephalic cyst with the FLAIR sequence

sity of CSF, which makes it difficult to detect lesions in a periventricular distribution.

4.3 Diffusion Weighted Imaging

Image contrast in diffusion weighted sequences depends on the molecular motion of water. These sequences are particularly useful for demonstrating early myelination before it can be seen with conventional sequences.⁹ It also shows regions of focal infarction and diffuse ischemic anoxic brain injury which are not visible on spin echo and inversion-recovery images in the early phase (see Section 9).

4.4 Magnetization Transfer Techniques

These sequences have proved useful for improving lesion contrast both for short and long T_1 lesions¹⁰ and in newborn infants the conspicuity of some cystic lesions is improved. It is also a useful technique for demonstrating myelination.

4.5 MR Angiography

MR angiography (MRA) is a noninvasive method of examining cerebral blood flow, although its use in pediatric practice has so far been limited. Cerebral blood flow is slow in infants and the blood vessels are smaller than in adults. A recent innovation in this technique has been the implementation of magnetization transfer MRA which involves the application of a specialized frequency-selective pulse followed by the desired MRA sequence. This results in a darkening of the background static tissue with an increase in contrast with the flowing blood. Our initial studies using two- and three-dimensional time-of-flight angiography have been of value in showing the internal carotid and basilar arteries and the proximal regions of the anterior, middle, and posterior cerebral arteries in the term infant (Figure 3). Large veins are also well shown.

4.6 The Gradient Echo (GE) and Partial Saturation (PS) Sequences

The gradient echo and partial saturation sequences have a specific role in pediatric practice, especially in the detection of neonatal hemorrhage. Low signal regions in and around hematomas are seen with higher sensitivity with partial saturation sequences than with spin echo sequences, indicating a significant contribution from susceptibility effects.¹¹ Phase maps can be derived from two partial saturation sequences with different values of TE , and are particularly useful for looking at the susceptibility effects of intracerebral hemorrhage.¹²

The use of these sequences in fast imaging techniques increases the speed of MR examinations, which is of particular interest when scanning infants; however, high signal from CSF remains a problem.¹³ A GE sequence with a TE of 29 ms and a flip angle that corresponds to the choice of TR is recommended at 1.5 T to optimize the detection of calcification in the brain.¹⁴

4.7 Volume Imaging

This may be of particular value in infants and children because reconstruction and reslicing of images can provide a

Figure 3 Three-dimensional time-of-flight (TR 44, TE 8) angiogram: an 18-month-old male infant with known infarction of the left middle cerebral artery. The anterior, posterior, and middle cerebral arteries are seen, but there is a paucity of vessels on the left in the anterior branches from the middle cerebral artery (arrows)

precise correction for differences in registration of follow-up examinations so that subtle differences in growth and development can be recognized.

5 NORMAL DEVELOPMENT AND MRI APPEARANCES

During the first 2 years of life the pediatric brain changes rapidly as physiological myelination takes place. This continues at a slower rate into the second decade. The process of myelination begins in utero and is first seen in the cerebellum and brainstem and then spreads from the posterior limb of the internal capsule to the postcentral gyrus. After birth, white matter develops in a predictable manner with sensory tracts myelinating before motor tracts from dorsal to ventral and from central to the peripheral areas of the brain.^{15,16} Several descriptions of this process with MRI using a variety of sequences are available in the literature.^{2,3,17-20} The pattern of development from 29 weeks gestational age to 1 year of age is shown by IR sequences in Figure 4.

5.1 Delays or Deficits in Myelination

Delays or deficits in myelination are difficult to recognize before 3-6 months of age, since relatively little myelin is present. Conversely, after 2 years of age there is time for cases of delayed myelination to 'catch up'. As a result, delays or defi-

Figure 4 Infant born at 29 weeks gestational age and examined at 31 weeks gestational age (IR 7096/30/1500). At the level of the diencephalon (a) no myelin is seen; however, the posterior limb of the internal capsule is seen as low signal intensity (arrows), the remaining white matter is featureless. The cortex is of high signal intensity and the gyral pattern is underdeveloped. At the level of the pons (b) the corticospinal tracts are of low signal intensity (SI); however, myelin is seen in the medial longitudinal fasciculus and the inferior cerebellar peduncle (arrows). Term infant (IR 3500/30/950) (c–d). At the level of the diencephalon (c) the cortex remains of higher SI than unmyelinated white matter, but more structure is seen than in (a). Myelination is present in the ventrolateral nuclei in the thalami and in the posterior limb of the internal capsule (arrows). The lentiform nuclei have relatively high signal compared to the caudate nuclei and the thalami. At the level of the pons (d) myelin is seen in the medial lemnisci (arrows). At the age of 2 months at the level of the pons (e) myelin is present in the corticospinal tracts (arrows) anterior to the medial lemnisci and further myelination is seen in the cerebellum. (f, g) Infant aged 12 months (IR 3200/30/800). At the level of the diencephalon (f) myelination is now seen throughout the internal and external capsule, along the occipitthalamic pathways and the corpus callosum. At the level of the mesencephalon (g) myelin is seen in the crus cerebri (arrows)

cits are most obvious from 6 to 24 months of age. With only limited information about the normal range we have preferred to use age-matched controls and diagnose delays only in the absence of or marked reduction in myelination of named tracts or commissures relative to controls, with both examinations performed using the same technique.

Delays or deficits in myelination have been recognized following probable intrauterine rubella infection, in posthemorrhagic hydrocephalus, after hypoxic ischemic encephalopathy, infarction, periventricular cystic leukomalacia, and metabolic disease.

6 INTRACRANIAL HEMORRHAGE

Intraventricular/periventricular hemorrhage (IVH/PVH) is the most important and most common type of hemorrhage in infants of less than 32 weeks gestation, with 90% of the hemorrhage occurring in the germinal matrix adjacent to the heads of the caudate nuclei.^{21,22}

The basal ganglia are the most vulnerable site for hemorrhagic lesions in term infants suffering from severe birth asphyxia.²² Ultrasound is used to detect and monitor the progression of IVH/PVH in the early stages in infants too sick to transport to the MR unit. However, MR is useful in the stable neonate²³ and for long-term follow-up. The MR appearance of hemorrhage parallels that seen in adults; however, in neonates hemorrhage occurs against a background of long normal values of brain T_1 and T_2 , so that the T_2 of hematoma may appear distinctly shorter than that of the surrounding brain (Figure 5).

The signal characteristics of subdural and extradural hematomas are similar to those seen in adults. Subarachnoid blood, especially along the Rolandic fissure, is a common finding in the newborn term infant (Figure 6).

Figure 6 Normal term infant examined at 24 hours of age (IR 3800/30/950). Note the high signal intensity of the subarachnoid blood along the Rolandic fissure (arrows)

The ability to demonstrate methemoglobin and hemosiderin by a shortening of T_2^* and susceptibility effects provides a high degree of sensitivity, and may function as a marker of early hemorrhage years after the event.²⁴ The late sequelae of intracranial hemorrhage may have important consequences such as hydrocephalus.

Figure 5 Female infant with IVH/PVH born at 26 weeks gestational age and examined at 40 weeks gestational age. (a) Inversion-recovery (IR 6000/30/1200) and (b) T_2 -weighted spin echo (SE 2700/120) sequences. Hemorrhage is seen as high signal intensity on the IR image (a), but is seen more clearly on (b) as low signal intensity (arrows). Myelin in the posterior limb of the internal capsule is better seen in (a) than in (b)

7 PERIVENTRICULAR LEUKOMALACIA

The second most frequent condition to afflict premature infants is periventricular leukomalacia (PVL),^{21,22} which occurs in a characteristic distribution in white matter around the lateral ventricles. Ultrasound scanning is generally used to make the diagnosis of leukomalacia; however, periventricular cysts and subcortical cysts are clearly seen with MRI in the early neonatal period and the changes can be quite extreme. Sometimes the cysts coalesce and become continuous with the adjacent ventricles producing hydrocephalus. The presence of severe or moderately severe cysts in infancy is frequently associated with a delay or deficit in myelination (Figure 7).

The MRI features are closely correlated with clinical outcome.²⁵ For example, infants with mild periventricular change on MRI have a mild spastic diplegia and normal intellectual development, whereas infants with subcortical cysts, diminution of white matter and microcephaly are severely mentally retarded with quadriplegia and seizures. In older children PVL is seen, with a T_2 -weighted spin echo sequence, as an increased signal intensity usually in white matter in the centrum semiovale and adjacent to the anterior and/or the posterior horns of the lateral ventricles. We have found greater conspicuity of the lesions with the FLAIR and the short TI inversion-recovery sequences. To date, MRI has been most useful for studying the late stages of cystic leukomalacia.²⁶ MRI also permits retrospective diagnosis of the condition in infants who were not scanned either during the neonatal period or were scanned at a stage of evolution when the cysts were not apparent.

Figure 7 Male infant with severe cystic periventricular leukomalacia born at 33 weeks and examined aged 11 months (IR 1800/44/600). There is a severe delay in myelination compared with that seen in Figure 4(f)

8 INFARCTION

Cerebral infarction is most commonly seen in term infants and appears as a region of increased T_1 and T_2 which may be difficult to distinguish from areas of unmyelinated white matter normally present in the brain. There may be a loss of gray-white matter contrast and loss of the normal gyral pattern in a focal area, with or without a slight increase in T_1 . The use of diffusion weighted imaging, where contrast is mainly determined by differences in the molecular motion of water (and not T_1 and T_2), may show the extent of the lesion within hours of the onset of injury (Figure 8).²⁷

However, 1–4 days after the onset of symptoms, changes in T_1 and T_2 occur and the region of infarction may become visible with standard imaging techniques. With increasing age there is some apparent shrinking of the lesion and a porencephalic cyst may develop. Some porencephalic cysts decrease in size, some remain the same size, and others appear smaller due to increasing head size (Figure 9). Associated hydrocephalus with porencephalic cysts communicating with the ventricles may produce an apparent increase in the size of cysts. Wallerian degeneration within the corticospinal tracts can be seen as early as 7 days after the insult in newborn infants, with atrophy of the brainstem occurring by 3 months of age. These findings occur much earlier in children than in adults.^{28,29}

9 HYPOXIC ISCHEMIC ENCEPHALOPATHY

Hypoxic ischemic encephalopathy (HIE) is most frequently seen in term infants²² and the pattern of damage and its evolution is very variable even in children who appear to be seriously affected immediately after birth. Specific early MR features include brain swelling and increased signal intensity on the inversion-recovery sequence in the cortex which is usually the most marked around the Rolandic fissure with decreased signal intensity on the T_2 -weighted spin echo sequence. Loss of the normal signal intensity in the posterior limb of the internal capsules as well as focal hemorrhagic lesions in the basal ganglia, which are most commonly located in the lentiform nuclei, are also seen (Figure 10).

Brain swelling is not seen after the first 4 days and the evolution of the early MR findings may include breakdown of white matter into subcortical cysts within the first 2 weeks of life, with diminution of white matter and a severe delay in myelination by 3 months of age. The basal ganglia lesions become less obvious with time and may regress completely. Development of myelination in the posterior limbs of the internal capsules may occur by 3 months of age. Alternatively, the lesions in the basal ganglia and thalami become cystic and this may occur as early as 17 days of age with atrophy of the basal ganglia by 6 weeks of age. The degree of cortical highlighting is also variable and diminishes with time; however, in our experience it may still be present up to 6 months of age.

Early diffusion weighted imaging is important in these children (Figure 11) and correctly predicts the sites of injury which become more obvious on standard imaging at a later stage. These striking early MR findings closely correlate with the location of the selective neuronal necrosis^{21,22} seen at post mortem in asphyxiated infants.

Figure 8 Cerebral infarction in a male infant born at 40 weeks gestational age. (a) Transverse T_1 -weighted spin echo (SE 720/20), (b) T_2 -weighted spin echo (SE 3000/120), (c) diffusion weighted (SE pulse interval/200 ms, A-P sensitization, $b = 600 \text{ s mm}^{-2}$), and (d) diffusion weighted (SE pulse interval/200 ms through plane sensitization, $b = 600 \text{ s mm}^{-2}$) images. The infarction is difficult to recognize on (a) or (b) but is readily apparent as a high signal region on (c) and (d) (arrows)

The prognosis for infants with global hypoxia can be devastating. However, new cerebroprotective drugs are at present undergoing investigation in stroke models, but these therapies are only effective in the first few hours after birth before the onset of secondary energy failure.³⁰ It is hoped that these MR findings may be used to monitor such treatment in the future.

10 HYDROCEPHALUS

Hydrocephalus can arise in a number of circumstances in children.³¹ The ventricular size can be readily assessed, and MRI has obvious advantages in the long-term follow-up of children with shunts. It is also possible to recognize periventricular edema both with spin echo and inversion-recovery sequences; this condition may regress following satisfactory ventricular shunting. The periventricular changes are displayed as increased signal intensity in the periventricular regions in some cases of hydrocephalus, probably indicating transependymal spread of fluid. We have found the STIR sequence (CSF displayed as moderate signal intensity) and the FLAIR sequence (CSF displayed as low signal intensity) are better than the conventional spin echo sequence for looking at periventricular change in children with hydrocephalus (Figure 12). However, similar changes may be seen in other diseases such as periventricular leukomalacia, and the changes are not

specific. It is not always possible to distinguish between acute and chronic hydrocephalus.

Hydrocephalus caused by aqueduct stenosis and other obstructive lesions is generally well displayed with MRI and the ability to scan in more than one plane is very useful in these conditions.

11 CONGENITAL MALFORMATIONS

Brain development follows a well defined sequence. A disturbance at any particular time may affect one or more stages and result in a developmental anomaly.^{2,3,32-34} Dorsal induction occurs during week 3-4 of gestation when the nasal plate folds to form the nasal tube. Failure to close caudally results in myelomeningocele, and failure to close at the cephalad end may result in anencephaly encephalocele, etc. In the next stage the mesencephalon divides to form the telencephalon. Failure at this stage produces prosencephaly. Normal proliferation then follows in which the germinal matrix forms the neurons that form the cortex. Neurons may fail to form the normal cortical layers, or stop along their path resulting in multiple cortical abnormalities including heterotopia.

Neurofibromatosis, tuberous sclerosis, and Sturge-Weber disease are the common neurocutaneous diseases occurring in children.³⁵ However, the MRI features may be difficult to define in the neonate, before some degree of myelination has

Figure 9 Infant aged 9 months with a left middle cerebral infarct. (a, c) Inversion–recovery (IR 3400/30/800) and (b) T_2 -weighted spin echo (SE 2700/120) images. A large porencephalic cyst is seen in the left hemisphere. Increased signal intensity is seen along the length of the posterior limb of the internal capsule in (b) and low signal intensity is seen in (a) (arrows). The mesencephalon on the left is smaller than on the right (c) (arrows). Less myelin is seen on the left hemisphere than on the right

taken place. MRI is of considerable value in demonstrating tumors associated with the phakomatoses as well as MRI regions of gliosis, hematomas, and cerebral atrophy.³⁶ Calcification in tuberous sclerosis is poorly shown, but may be seen.³⁷ Computed tomography (CT) or plain skull X-rays may be more useful in this situation.

Obvious anatomical deformations are readily shown, e.g. anencephalopathy, holoprosencephaly, and Dandy–Walker syndrome. The sagittal plane lends itself to demonstration of many of these conditions including, for example, agenesis of the corpus callosum.

12 WHITE MATTER DISEASE

The most common white matter disease to affect infants is periventricular leukomalacia (see Section 7). Recognition of other white matter disease is difficult in early life because of the lack of myelin present at birth and in the first 6 months of life. Once myelin has been laid down it can disappear in two principal ways, namely demyelination and dysmyelination.³⁸ In demyelination the breakdown of myelin is caused by extrinsic factors (e.g. infection, trauma, chemotherapy), and in dysmyeli-

Figure 10 Male infant born at 40 weeks with severe birth asphyxia: T_1 -weighted spin echo (SE 860/20). Images at age 2 days (a) and 10 days (b); (c) inversion-recovery (IR 3797/30/95) image at age 5 weeks; (d) IR 3405/30/800 at age 6 months. At age 2 days brain swelling is present and there is a loss of sulcal patterns and gray-white matter contrast. The ventricles and the interhemispheric fissure are small (a). At 10 days, the brain swelling is no longer present. High signal intensity is seen throughout the cortex and the white matter is featureless. Hemorrhagic lesions are seen with the globus pallidus (arrows). There has been loss of the normal increased signal intensity in the posterior limb of the internal capsule (b). At 5 weeks (c) there has been a diminution in white matter and cystic change is noted in the posterior limb of the internal capsule. At 6 months (d), there has been further loss of white matter relative to normal. Abnormal signal intensity is seen in the thalami and globus pallidus. Further myelination has taken place

nation there is a genetic disorder of myelin formation which is a feature of metabolic disorders such as the leukodystrophies. Diffuse abnormalities are seen within white matter in leukodystrophy. The changes are usually extensive and not confined to the periventricular region. In other forms of white matter disease, such as Alexander's disease, changes may be confined to the frontal lobes. A variety of other abnormalities have been described in different forms of leukodystrophy.^{2,38} We have also seen periventricular abnormalities associated with intrathecal methotrexate therapy in leukemia. Along with delays in myelination, both demyelination and dysmyelination are readily recognized on MRI in children.^{2,38,39}

13 INFECTION

Excellent reviews on inflammatory diseases of the brain in childhood are available in the literature.^{2,40} Cerebral abscess

displays an increase in T_1 and T_2 . Edema is well displayed but the exact margins of the abscess may be difficult to define.⁴⁰ However, ring enhancement after the intravenous injection of gadolinium diethylenetriaminepentaacetic acid (Gd-DTPA) may help in the differential diagnosis of cerebral abscess. Calcification associated with abscess is poorly demonstrated in comparison with CT.

In two cases of brainstem encephalitis, changes have been seen with very little associated mass effect. This has been the main distinction between tumors at the initial examination and on regression on follow-up examination. It provides strong support for the diagnosis, although a certain amount of caution is necessary as patients are frequently treated with steroids which may result in some regression of edema associated with a tumor. In a case of cytomegalovirus, marked white matter change has been observed in a child of 2 years without any overt clinical signs (Figure 13). In neonatal meningitis, contrast enhancement may be seen in the meninges (Figure 14).

Figure 11 Hypoxic ischemic encephalopathy on day 1: (a) transverse T_1 -weighted spin echo (SE 720/20), (b) T_2 -weighted spin echo (SE 3000/120) (c) diffusion weighted (SE pulse interval/200 ms, left-right sensitization, $b = 600 \text{ s mm}^{-2}$), and (d) diffusion weighted (SE pulse interval/200 ms, through-plane sensitization, $b = 600 \text{ s mm}^{-2}$) images. High intensity signal is only seen in the medial right occipital lobe in (b) (arrows), suggesting the diagnosis of infarction; much more extensive abnormalities are seen bilaterally in the frontal, temporal, and occipital lobes using diffusion weighted imaging (c and d) (arrows showing some of the high intensity signal areas)

14 TUMORS

In general, the features of tumors in children parallel those in adults; however, there is a higher incidence of tumors in the posterior fossa, and embryological tumors are more common.² The high incidence of midline tumors lends itself to sagittal imaging, and the clarity with which the posterior fossa is seen is also an advantage.

Most tumors display an increased T_1 and T_2 providing high contrast with long TE long TR spin echo sequences, although distinction between tumor and edema may be difficult. Differentiation between brainstem and cerebellar sites is reasonably easy. Craniopharyngiomas and various other lipid-containing tumors may show characteristic features. Hamartomas may not display a significant change in T_1 and T_2 and may then need to be recognized by their indirect signs. Hypothalamic tumors which may be poorly seen with CT are well recognized with MR.

15 OTHER DISEASE

Certain other conditions are worth reviewing, although they are quite rare. Delays or deficits in myelination have been

recognized in Hurler's disease, and these may be reversed following successful bone marrow transplantation.⁴¹

Hallervorden-Spatz disease is of particular theoretical interest as a condition in which there is abnormal iron deposition in the brain, and in one case abnormalities have been seen in the basal ganglia.

In Wilson's disease abnormalities are seen in the lentiform nucleus and within the thalamus;⁴² however, the findings are not specific as similar changes are seen in children with Leigh's disease.²

16 FOLLOW-UP EXAMINATIONS

This is an important aspect of pediatric practice. The normal appearances including the value of T_1 and T_2 , the presence of periventricular long T_1 areas, the degree of myelination, as well as the size and the shape of the brain, all change. Pathological changes must be assessed against this changing background.

The lack of known hazard is a strong incentive for pediatric MRI. Follow-up examinations in conditions in which long-term survival is expected without accumulating significant X-ray dosage is important. Nevertheless, there are problems in achieving MRI scans at the same level and angulation as in the

Figure 12 Male infant aged 2 years with posthemorrhagic hydrocephalus: (a) mildly T_2 -weighted (SE 2500/20) and (b) moderately T_2 -weighted (SE 2500/80) spin echo sequences; (c) fluid attenuated inversion-recovery sequence (FLAIR 6500/160/2100). A shunt artifact is seen. There is an increase in signal intensity around the lateral ventricles in (a), which is less well seen in (b) and best seen in (c) (arrows)

initial studies. There is also a theoretical problem in using age-adjusted sequences since the machine parameters are different. Genuine advances in technique can also make comparison difficult.

17 CONCLUSIONS

Developments in pediatric MRI lag behind those of adults, but it is possible to extrapolate findings in adults to children. Clinical correlation has been progressing, but the correlation is not precise and some children may have very large lesions

with relatively small clinical deficits. Large unsuspected lesions have been found where the clinical signs are quite subtle. The capacity for repeated examination without cumulative radiation dosage problems has been of value in studying the natural history of a variety of neonatal insults.

The versatility of MRI with its basic image parameters ρ , T_1 , T_2 , chemical shift, flow, susceptibility, and diffusion effects provides a wide variety of options for the various problems encountered in clinical practice. Only a small number of these options has yet been employed in pediatric practice, and a growing role for MRI in this area is certain. The application of MR may be greatly expanded by the installation of suitable

Figure 13 Female infant aged 2 years with cytomegalovirus; fluid attenuated inversion–recovery (FLAIR 6500/160/2100) sequences. Areas of long T_2 are seen throughout the white matter

Figure 14 Male infant aged 6 weeks with meningitis. T_1 -weighted spin echo (SE 720/20) sequence before (a) and after intravenous injection of Gd-DTPA (b). Meningeal enhancement is seen in (b) (arrows)

systems in neonatal intensive care units. To date only relatively large and stable infants have been examined, but the impact of MRI on the management of the critically ill and very premature infants may be much expanded in the future.

Jacqueline M. Pennock. b 1940. M.Phil., 1976. Department of Diagnostic Radiology, Hammersmith Hospital, London 1963-present. Currently, senior scientific officer. Approx. 80 publications. Metabolic and endocrine disease (with Professor Frank Doyle). Current research interests: pediatric magnetic resonance, specifically related to normal development and critically ill preterm and term infants (with Frances Cowan, Mary Rutherford, Lilly Dubowitz and Graeme Bydder).

Pituitary Gland and Parasellar Region Studied by MRI

Richard Farb and Walter Kucharczyk

University of Toronto, Toronto, ON, Canada

1 ANATOMY AND THE MRI TECHNIQUE

The pituitary gland is a small but important organ situated in a small bony depression in the skull base called the sella turcica. Although the average weight of the pituitary gland in the adult is only 0.5 g, it is responsible for the regulation of many of the body's most critical endocrine functions. The gland enlarges slowly with maturation reaching a peak height of no more than 9–10 mm in early adulthood. There are two periods when the gland may transiently enlarge beyond its normal dimensions, those being adolescence and pregnancy. This is principally due to physiological hypertrophy of prolactin-secreting cells.

The pituitary gland is made up of three distinct lobes: anterior, intermediate, and posterior. The intermediate lobe is a vestigial remnant in humans and serves no function; however, it may be the site of an incidental cyst. The anterior lobe, or adenohypophysis, is a true endocrine organ responsible for synthesizing many hormones. Its function is regulated by stimulatory and inhibitory hormones arising from the hypothalamus. The posterior lobe of the pituitary gland, also called the neurohypophysis, is actually a downward extension of the hypothalamus. The hormones of the posterior pituitary gland, vasopressin and oxytocin, are synthesized within the hypothalamus and axonally transported to the posterior pituitary gland where they are stored and from which they are ultimately released.

The anterior and posterior lobes of the pituitary gland are therefore two functionally distinct entities, although they reside in very close association within the sella turcica. The posterior lobe is much smaller than the anterior lobe and takes up only 10–20% of the sella turcica. The anterior lobe of the pituitary gland generally takes up the anterior, central, and lateral aspects of the sella turcica. The posterior lobe resides centrally in the midline just anterior to the dorsum sella. The lateral wings of the adenohypophysis usually extend laterally around the posterior pituitary gland.

The anterior and posterior lobes of the pituitary gland are easily distinguishable on MRI. The anterior lobe of the pituitary gland is normally isointense with cerebral white matter on all pulse sequences, whereas the posterior lobe of the pituitary gland is easily distinguishable by its characteristic hyperintense signal on T_1 -weighted images. Following the administration of intravenous contrast material the anterior and posterior lobes, as well as the pituitary stalk, enhance intensely.

The pituitary gland is enclosed within the sella turcica by a dural diaphragm (the diaphragma sella), the center of which

has a defect in it allowing for passage of the pituitary stalk. The superior surface of the diaphragma sella is lined with arachnoid, and the suprasellar cistern lies above the diaphragma sella. The suprasellar cistern contains all the vascular structures of the circle of Willis. The optic chiasm is immediately anterior to the pituitary stalk (infundibulum) within the suprasellar cistern.

On either side of the sella turcica lie the cavernous sinuses. These are complex dural venous sinuses passing from the anteromedial aspect of the posterior fossa (Meckel's cave) anteriorly to the superior orbital fissure, transmitting cranial nerves III, IV, V1, and V2 within the lateral walls of the cavernous sinus. Cranial nerve VI is the only cranial nerve that actually passes within the cavernous sinus. The appearance of the cavernous sinuses on MRI is somewhat variable in signal intensity; however they are usually symmetric in dimensions. Following contrast administration the cavernous sinuses enhance intensely. The normal MRI anatomy is illustrated in Figure 1.

Imaging of the pituitary gland and sella turcica for possible structural abnormalities is a frequent indication for MRI. Exact specifications of the technique are not provided here because the constantly improving capabilities of modern scanners require that technique be continually revised. However high spatial detail is very important in this area and should be achieved through the use of thin slices, a fine matrix size, and a relatively small field-of-view. Requirements for spatial detail must be balanced against the need for adequate signal-to-noise ratio as well as imaging time.

The pulse sequence for best tissue contrast is still a matter of opinion. Several groups have shown that short TR , short TE spin echo images (i.e. T_1 -weighted) generate very good contrast for visualizing pituitary pathology.^{1,2,3} Because fast spin echo (FSE) methods are now readily available, and do not incur the time penalty of conventional T_2 -weighted spin echo sequences, coronal T_2 -weighted FSE imaging is being utilized with increasing frequency as a supplementary sequence for investigation of pituitary adenomas. Several other pulse sequences have been implemented for parasellar imaging and have met with varying degrees of success.⁴

Paramagnetic contrast-enhanced images are widely used and are very useful. Although most adenomas are visible without the injection of intravenous contrast, several studies have shown that small adenomas may become visible only after contrast injection.^{5,6} To take better advantage of the differential rates of contrast enhancement between adenomas and normal pituitary gland, dynamic pituitary scanning immediately after bolus contrast injection is also useful.⁷

2 CONGENITAL ABNORMALITIES

2.1 Pituitary Gland Hypoplasia

Congenital abnormalities of the pituitary gland and hypothalamus are usually present in association with anomalies of other midline cranial, orbital, and facial structures. Pituitary gland hypoplasia is usually accompanied by a small sella turcica, and is commonly clinically associated with growth failure and other endocrine abnormalities. A curious form of pituitary hypoplasia has recently been recognized to occur with a

Figure 1 Normal MR anatomy of the pituitary region. T_1 -weighted sagittal (a), and coronal (b), images. A. Anterior pituitary gland, B. optic chiasm, C. cavernous sinus, D. pituitary stalk, E. right internal carotid artery (supraclinoid portion), F. left internal carotid artery (cavernous portion), G. medial temporal lobe, H. sphenoid sinus, I. hypothalamus, J. trigeminal nerve, K. pterygoid canal, L. sylvian fissure, M. mammillary body, N. frontal lobe, O. midbrain, P. pons, Q. medulla, R. interpeduncular cistern, S. genu of corpus callosum, T. tuber cinereum, U. cerebral aqueduct, V. third ventricle, W. posterior pituitary gland

slightly higher frequency in patients with a history of breech deliveries.⁸⁻¹⁰ These patients have short stature and growth hormone deficiency, as well as the MRI findings of pituitary hypoplasia, hypoplasia of the distal pituitary stalk, and absence of the normal hyperintensity within the posterior pituitary gland.

2.2 Ectopic Posterior Pituitary Tissue

Occasionally, the normal hyperintensity on T_1 -weighted images within the posterior pituitary gland and in the posterior aspect of the sella turcica is not visualized. Instead there is a small area of hyperintensity seen along the course of the pituitary stalk. This may be associated with discontinuity of the pituitary stalk. These patients may present with hormonal abnormalities, particularly of the anterior pituitary gland, due to transection of the hypothalamo-pituitary portal anastomosis. It is rare for these patients to present with posterior pituitary gland hormonal deficiencies.

'Ectopic posterior pituitary tissue' is thought to occur by one of two mechanisms, either incomplete embryologic descent of hypothalamic neurons, or possibly due to traumatic transection of the pituitary stalk above the diaphragma sella. In either case, the neurosecretory granules descending down toward the posterior pituitary gland from the hypothalamus accumulate within the proximal stump of the amputated pituitary stalk. This simply becomes the new site or location of posterior pitu-

itary tissue thus accounting for the increased signal intensity on T_1 -weighted images as well as the normal hormonal profile of the posterior pituitary gland.

2.3 The Empty Sella Turcica

The terms 'empty sella syndrome' or 'empty sella turcica' refer to the roentgenographic, pneumoencephalographic, or computed tomographic appearance of the sella turcica, which is filled predominantly with cerebrospinal fluid (CSF), with the normal posterior pituitary gland and stalk being crowded posteriorly and inferiorly within the sella turcica. The cause of this displacement is the presence of a large defect in the diaphragma sella allowing the arachnoid membrane to herniate through the diaphragma sella adjacent to the stalk and thus allowing CSF pulsations to enter the sella turcica and result in the eventual displacement of the pituitary gland and stalk posteriorly. It is actually quite rare for patients with an 'empty sella' to have symptoms referable to the area of the sella turcica. 'The empty sella' is most commonly seen as an incidental finding of little or no clinical significance.

2.4 Cephaloceles

Cephaloceles are herniations of the meninges (meningocele) or of the meninges and the brain (meningoencephalocele) through a congenital cranial defect. Cephaloceles in the sellar

region (transphenoidal encephaloceles) are very rare. Most of these are associated with other midline anomalies, particularly agenesis of the corpus callosum.

3 TUMORS AND TUMOR-LIKE CONDITIONS

3.1 Pituitary Adenoma

The most common tumors affecting the pituitary gland are pituitary adenomas. These are benign, slow growing, epithelial adenomas originating in the adenohypophysis. Pituitary adenomas are usually well demarcated lesions that are separated from the normal pituitary gland by a pseudocapsule of compressed tissue. Pituitary adenomas are commonly classified based on size and hormonal activity. Adenomas measuring greater than 1 cm in diameter are referred to as **macroadenomas**; those less than 10 mm are **microadenomas**. Those adenomas that are hormonally active may also be referred to by the hormone that they secrete. For example, the most common hormonally active adenoma is the 'prolactin-secreting microadenoma', or simply prolactinoma. The various hormonal types of adenomas are indistinguishable from one another by MRI imaging.

On MRI, pituitary microadenomas are usually small, focal hypointensities within the pituitary gland on T_1 -weighted images. On T_2 -weighted images the corresponding lesion is seen as hyperintense to the surrounding pituitary tissue.³ Approximately 80–95% of pituitary adenomas present with these characteristic signal intensities (Figure 2). Intratumoral hemorrhage occurs in 20–30% of adenomas. These are usually macroadenomas (Figure 3). The incidence of intratumoral bleeding is higher in patients receiving bromocryptine therapy.¹¹ We have found that tumors that are hyperintense on T_1 -weighted images are always cystic with the cyst containing elements of previous hemorrhage.

Tissue contrast represented by a differential signal intensity between the tumor and normal pituitary gland is the most sensitive and reliable indicator of the presence of a microadenoma (Figure 2). Indirect signs previously utilized for computed tomography imaging of the pituitary gland such as tilt of the pituitary gland, contour of the superior aspect of the pituitary gland, and deviation of the pituitary stalk, all appear to be quite insensitive to the presence of microadenomas and indeed may be misleading (Figure 2).

It is difficult to determine the accuracy of MRI for the diagnosis of pituitary microadenomas. It is estimated that about 90% of microadenomas are detected and accurately localized with MRI.³ The detection rate of macroadenomas approaches 100%. Their signal intensities are qualitatively similar to their smaller counterparts; however they more commonly demonstrate cystic degeneration or hemorrhage.

An area of continued difficulty in pituitary and parasellar imaging is that of the postoperative examination in search of residual or recurrent pituitary adenoma. In these cases, it may be very difficult to distinguish postoperative scarring, or graft material, from the normal gland or adenomatous tissue. This is especially true in the first 6 months after surgery. In these cases, progressive growth of a soft tissue mass on sequential postoperative MR scans is the best imaging sign of recurrent

tumor. This must also be interpreted in conjunction with endocrinologic markers.

3.2 Craniopharyngioma

Craniopharyngiomas are epithelial-derived neoplasms thought to arise from remnants of Rathke's cleft in the region of the pars tuberalis. They account for 3% of all intracranial tumors and show equal incidence in males and females. Tumors can vary greatly in size from several millimeters to several centimeters in diameter with the epicenter of the tumour usually located in the suprasellar cistern. Craniopharyngiomas typically have both solid and cystic components (Figure 4). Calcification is commonly seen in the solid portion of the tumor. The cystic contents of the tumour can vary in color and viscosity.

On MRI craniopharyngiomas are typically lobulated with heterogeneous signal intensities on T_1 - and T_2 -weighted images.¹² The cystic component of the tumor is uniform and commonly hyperintense on both T_1 - and T_2 -weighted images, and contains fluid that has been likened to 'machine oil'.

3.3 Rathke's Cleft Cyst

Rathke's cleft cysts share a common origin with craniopharyngiomas in that they originate from remnants of squamous epithelium of Rathke's cleft. The cysts are common incidental findings at autopsy; however the larger cysts can be symptomatic. The contents of the cysts are typically mucoid. Less commonly they are filled with serous or desquamated cellular debris.¹³ The mucoid-containing cysts can be hyperintense on T_1 and T_2 -weighted images; the serous-containing cysts have signal intensities that closely match CSF (Figure 5). Rathke's cleft cysts do not enhance following contrast injection, except for perhaps marginal enhancement around the cyst wall. If nodular enhancement or calcification is seen, craniopharyngioma should be suspected.

3.4 Meningioma

Approximately 10% of meningiomas occur in the parasellar region. These tumors arise from a variety of locations around the sella including the tuberculum sellae, clinoid processes, medial sphenoid wing, and cavernous sinus. Meningiomas are most frequently isointense relative to gray matter on unenhanced T_1 -weighted images. Approximately 50% remain isointense on T_2 -weighted images.^{14,15} Meningiomas, as well as other extraaxial tumors, can demonstrate a typical CSF cleft between the tumor and the adjacent brain parenchyma. Also, meningiomas have been noted to demonstrate a peripheral black rim around their margins, thought to represent veins surrounding the tumor.

Meningiomas commonly encase arteries of the parasellar region, particularly the cavernous and supraclinoid portions of the internal carotid artery. Meningiomas will typically narrow the vessels they encase (Figure 6). Adenomas, though they commonly encase vessels, usually do not narrow these vessels. Other distinguishing features of meningiomas include intense enhancement with intravenous contrast, tumor calcification, and hyperostosis of adjacent bone.

Figure 2 Pituitary microadenoma. (a) T_2 -weighted, (b) T_1 -weighted, and (c) enhanced T_1 -weighted images. This 40-year-old female was noted to have marked elevation of cortisol in the blood and urine due to this hormonally active tumor secreting adrenocorticotrophic hormone. This tumor demonstrates the typical features of a microadenoma including hyperintensity on T_2 -weighted images and hypointensity on T_1 -weighted images. Note the differential signal intensity between the intensely enhancing normal, anterior pituitary gland and the less enhancing tumor. Note also how the pituitary stalk deviates toward the tumor, thus stressing the unreliability of contralateral stalk deviation as a lateralizing sign of tumor

3.5 Germinoma and Teratoma

Germinomas account for less than 2% of primary intracranial tumors. Most of these tumors occur in the pineal region. However, approximately 20% of these tumors occur in the suprasellar cistern or pituitary fossa. Suprasellar germinomas occur either as metastatic deposits from a pineal region tumor or arise primarily in the suprasellar cistern. Most patients present between 5 and 25 years of age. Although pineal region germinomas are most commonly seen in males, there is no sex

predilection for the primary suprasellar germinoma. Other tumors of germ cell origin occurring in this region, albeit rarely, include yolk sac tumors, choriocarcinoma, embryonal cell carcinoma, and teratoma. Suprasellar germinomas are usually large midline tumors with a propensity to infiltrate and spread by the CSF pathways. In contrast to craniopharyngiomas, germinomas are homogeneous and only rarely have cystic components. Germinomas are mildly hypointense on T_1 -weighted images and hyperintense on T_2 -weighted images. Marked uniform contrast enhancement is the rule (Figure 7).

Figure 3 Pituitary macroadenoma. Nonenhanced T_1 -weighted image demonstrating a large, lobulated tumor occupying the sella and extending superiorly into the suprasellar cistern displacing the optic chiasm (A) superiorly. A focal area of increased signal intensity represents a small hemorrhage within the tumor. The tumor only abuts and does not clearly invade the cavernous sinus regions bilaterally

Teratomas have mixed heterogeneous signal intensities, often demonstrating evidence of fat or calcification.

3.6 Epidermoid and Dermoid

Epidermoids and dermoids are benign, slow-growing 'inclusion tumors' that can occur intracranially or intraspinally resulting from inclusions of epithelium during the time of neural tube closure. Dermoids are approximately one-fifth as common as epidermoids. Epidermoids account for approximately 1% of all intracranial neoplasms. The cerebellopontine angle is the most frequent site for epidermoids with the parasellar region being the second most common site.

Epidermoids are generally cystic tumors with the walls composed of simple, stratified, squamous epithelium resting on a layer of connective tissue. The interior of the cyst is composed of desquamated keratin products of the cyst wall. These tumors are benign and grow slowly with expansile characteristics. They also typically insinuate within and around structures, or conform to the space within which they are situated. Rarely the cyst can rupture producing a chemical granulomatous meningitis. Epidermoids are typically only slightly hyperintense to CSF on T_1 - and T_2 -weighted images, making the proton density image the most valuable sequence for identification of the epidermoid tumor. Epidermoids are characteristically hyperintense to brain and CSF on the proton density sequence.¹⁶ Unfortunately epidermoids can also retain signal intensities identical to CSF making them nearly indistinguishable from arachnoid cysts. Enhancement, if it occurs, occurs only along the periphery of the tumor. Dermoids are more heterogeneous. Most

dermoid tumors show evidence of fatty component as well as small areas of calcification.

3.7 Metastases

Metastases to the pituitary gland are a common autopsy finding but only about 1–2% of cancer patients have symptomatic metastases to the pituitary gland. These are usually metastases from breast or bronchogenic carcinoma.

3.8 Chordoma

Chordomas are rare neoplasms arising from remnants of the primitive notochord. Most cranial chordomas are found in the midline in relation to the clivus. Chordomas are locally invasive and destructive and commonly result in large, lobulated, destructive lesions extending in an extradural fashion. Portions of the sella and the parasellar regions are commonly involved. Chordomas are characteristically isointense or hypointense on T_1 -weighted images and hyperintense on T_2 -weighted images¹⁷ with moderate enhancement following intravenous contrast administration.

Figure 4 Craniopharyngioma. T_1 -weighted, enhanced, midline sagittal image of the parasellar region in this 3-year-old male demonstrating the typical findings of a craniopharyngioma. Note the enhancing solid tumor A, and the large cystic portion of the tumor B, extending supero-posteriorly, draping over the dorsum sella into the posterior fossa displacing the pons, C

Figure 5 *Rathke's cleft cyst.* T_1 -weighted, enhanced coronal image of the sella region demonstrating a somewhat bilobed cystic mass **A**, extending from the sella into the suprasellar cistern through the diaphragma sella **B**, displacing the optic chiasm superiorly **C**. This 28-year-old male presented with bitemporal hemianopsia and normal pituitary function. This typical appearance of the Rathke's cleft cyst has been likened to the appearance of a snowman

3.9 Arachnoid Cysts

Approximately 15% of arachnoid cysts occur in the juxtaseellar region.¹⁸ Suprasellar arachnoid cysts are thought to be developmental in origin and arise from an imperforate membrane of Liliequist. They have MRI characteristics identical to normal CSF.

3.10 Hamartoma of the Tuber Cinereum

Hamartomas of the tuber cinereum are sessile or pedunculated masses extending inferiorly from the hypothalamus into the suprasellar cistern between the pituitary stalk and mammillary bodies. Histologically they resemble cerebral cortex with little histologic similarity to the normal hypothalamus. Hamartomas of the tuber cinereum can be associated with precocious puberty. On MRI hamartomas are isointense to gray matter on all imaging sequences and should not enhance with contrast material (Figure 8).¹⁹

3.11 Eosinophilic Granulomatosis (Histiocytosis X, Langerhan's Cell Granulomatosis)

Histiocytosis can involve the pituitary gland, pituitary stalk, or hypothalamus. Twenty-five per cent of cases develop the classical clinical triad of diabetes insipidus, exophthalmos, and lytic bone lesions (the Hand-Schüller-Christian syndrome). In these cases granulomas can be found in the hypothalamus or the pituitary stalk. With MRI there is thickening of the pituitary stalk, hyperintensity on T_2 -weighted images, and intense enhancement following contrast administration.^{20,21}

4 INFECTIONS AND INFLAMMATORY CONDITIONS

4.1 Infections

Infections of the pituitary gland are a rare occurrence. Previous viral infection has been proposed as an etiology for diabetes insipidus. Leptomenigeal tuberculosis at the base of the brain can involve the pituitary gland. Bacterial infection of the pituitary gland is usually unnoticed until it manifests as a pituitary abscess, an entity which is also exceedingly rare. Pituitary abscesses are most frequently seen in association with preexisting conditions such as craniopharyngioma or pituitary adenoma. Transphenoidal surgery is rarely complicated by infection.

Infection of the parasellar regions, in particular the cavernous sinus is also very rare. Cavernous sinus thrombophlebitis is thought to be secondary to venous spread of a septic embolus from a periorbital or perinasal source.

4.2 Lymphocytic Hypophysitis

Lymphocytic hypophysitis is characterized by diffuse infiltration of the adenohypophysis by lymphocytes. It is most

Figure 6 *Meningioma.* This T_1 -weighted, enhanced coronal image demonstrates a homogeneously enhancing meningioma arising from the left anterior clinoid. Note the encasement of the left supraclinoid internal carotid artery, which is slightly narrowed when compared with the cavernous portion of the artery

Figure 7 *Germinoma*. T_1 -weighted, midline, sagittal, enhanced image demonstrating homogeneously enhancing masses within the pineal region A, and suprasellar region B. The presence of tumors in both the pineal and suprasellar regions is highly characteristic of germinoma

commonly seen in late pregnancy or the postpartum period, and has been associated with other autoimmune disorders such as Hashimoto's thyroiditis. Clinically the woman complains of headache, visual loss, and failure to resume normal menstrual cycle. MRI demonstrates diffuse enlargement of the anterior pituitary gland without focal abnormality.

Figure 8 *Hamartoma of the tuber cinereum*. T_1 -weighted, enhanced, midline sagittal image demonstrating a homogeneous mass located posterior to the pituitary stalk and anterior to the mammillary bodies, extending from the region of the tuber cinereum into the posterior aspect of the suprasellar cistern. This mass did not enhance and remained isointense to gray matter on all sequences, demonstrating the typical findings of hamartoma of the tuber cinereum

4.3 Sarcoidosis

Sarcoidosis most commonly occurs in an intrathoracic location. Any part of the central nervous system however can also be involved and 5% of patients with sarcoidosis will have neurologic complaints. The most typical findings for neurosarcoidosis include a basal meningitis with an abnormal, thick, enhancement pattern involving particularly the leptomeninges at the base of the brain characteristically in the midline. Abnormal parenchymal lesions are also noted within the brain. Neurosarcoidosis can be indistinguishable from other causes of leptomeningeal disease, in particular tuberculosis and leptomeningeal carcinomatosis.

4.4 Tolosa-Hunt Syndrome

This syndrome consists of painful ophthalmoplegia associated with a lesion within the cavernous sinus which is responsive to steroid therapy. Pathologically the lesion is similar to orbital pseudotumor.

5 VASCULAR LESIONS AND INFARCTION

5.1 Aneurysms

The large arteries in the suprasellar region are a common site of aneurysms. Aneurysms are for obvious reasons extremely important lesions to identify correctly. Fortunately their MRI appearance is distinctive and easily appreciated.^{22,23} Aneurysms centrally contain signal void created by rapidly flowing blood. This flowing blood may also cause a substantial ghosting artifact in the phase-encoding direction, which is a useful diagnostic sign. Thrombus within the aneurysm is laid down against the wall in a sequential fashion over a long period of time and results in a typical laminated appearance. Hemosiderin staining of the adjacent brain can also be seen. If confusion persists regarding the diagnosis, conventional angiography remains the gold standard for diagnosis of intracranial aneurysms.

5.2 Carotid Cavernous Fistulas

Carotid cavernous fistulas (direct or indirect type) can be spontaneous, posttraumatic, or atherosclerotic. Dural arteriovenous malformations of the cavernous sinus are another form of abnormal venous communication in this region. On MRI, dilatation of the venous structures, in particular the ophthalmic vein and cavernous sinus, is usually clearly visible. The carotid artery can also be somewhat dilated.

5.3 Postpartum Pituitary Necrosis

During pregnancy the pituitary gland increases in size thus making it vulnerable to circulatory disturbances. Postpartum ischemic necrosis of the pituitary gland is a well-known entity, which can follow complicated deliveries associated with hemorrhage and shock.

6 MISCELLANEOUS CONDITIONS

6.1 Diabetes Insipidus

Diabetes insipidus results from the lack of appropriate release of antidiuretic hormone (vasopressin) from the posterior pituitary gland. This results in the inability to concentrate urine and causes polydipsia and polyuria. The inability to release vasopressin in response to normal stimuli can have several possible etiologies: (1) primary failure to synthesize the hormone in the periventricular nuclei of the hypothalamus, (2) destruction of these nuclei or proximal transport pathways in the hypothalamus and proximal pituitary stalk, (3) dysfunction of hypothalamic osmoreceptors such that despite adequate vasopressin reserves, the hormone is not released appropriately. The causes of diabetes insipidus include neoplasms, infiltrative disorders, surgery, and head trauma. Approximately 30% of cases are idiopathic. MRI is valuable in demonstrating not only the causative lesions, but also the status of the posterior pituitary gland, the storage site for the neurosecretory vesicles containing vasopressin. It is a unique feature of this gland that it is hyperintense on T_1 -weighted images and regardless of the etiology this signal disappears in cases of diabetes insipidus.

6.2 Hemochromatosis

Hemochromatosis is a metabolic disorder in which excess iron is deposited throughout the body particularly in the solid abdominal viscera. For unknown reasons the pituitary gland is frequently involved. There is relative preferential deposition of iron within the gonadotrophic cells of the adenohypophysis. Dysfunction commonly manifests as loss of libido and hypogonadism. The characteristic finding on MRI is marked hypointensity emanating from the anterior pituitary gland on T_2 -weighted images. This is due to the high levels of iron deposited within the region resulting in susceptibility effects and loss of signal.²⁴

Biographical Sketches

Richard I. Farb. b 1959. B.Sc., 1981, University of Toronto. MD, 1985, University of Toronto, Canada. Radiology residency, Wayne State University Medical Center, Michigan 1991. Certification by examination by the Royal College of Physicians (Canada) and the American Board of Radiology 1991. Two year Neuroradiology Fellowship at University of Toronto completed 1993. Currently staff neuroradiologist at Sunnybrook Health Science Centre and lecturer at University of Toronto.

Walter Kucharczyk. b 1955. MD, 1979, University of Toronto, Canada. Radiology residency, University of Toronto, completing in 1983. Certified by examination as a Fellow of the Royal College of Physicians (Canada) in 1983, followed by two years of Neuroradiology MRI post residency training at UCSF and University of Toronto. Successively, visiting assistant professor (UCSF), assistant professor, full professor (University of Toronto). Currently Professor and Chair of the Department of Medical Imaging at the University of Toronto. Main interests: MRI of pituitary gland and parasellar area, tissue characterization using MR techniques, interventional methods with MRI.

Sodium-23 Magnetic Resonance of Human Subjects

Peter M. Joseph

Hospital of the University of Pennsylvania, Philadelphia, PA, USA

1 INTRODUCTION

Sodium-23 is a nucleus with spin quantum number $\frac{3}{2}$ whose gyromagnetic ratio, γ , corresponds to a frequency of 11.262 MHz tesla⁻¹, which is approximately one-quarter that of protons. It is widely but inhomogeneously distributed in body tissues. It is present in highest concentrations in extracellular water in a concentration of about 150 mM. Hence in vivo sodium NMR signals are less than one-thousandth those of hydrogen so that sodium MR images can never hope to compete with proton images in quality. Only little preliminary research effort has been directed toward the clinical utility of sodium MRI.

However, Na MRI may be able to contribute unique medical/physiological information that is not available in proton MRI. Intracellular Na is typically at the level of about 10–20 mM in most healthy cells. The enormous difference between intracellular (IC) and extracellular (EC) concentrations is maintained by the Na–K pump which actively transports the two kinds of ions across the cell membrane. Certain pathologies alter the function of that pump resulting in a significant rise in IC Na. There is evidence from in vitro experiments that this occurs in certain disease states, especially ischemia, infarction, and cancer. Thus one aim of Na MRI is to demonstrate a rise in the IC sodium concentrations. While there is still debate as to whether that goal has been achieved with in vivo MRI, it is one of the factors driving research interest in this field. There are various subtle aspects of the Na NMR signal that are thought to differ in the IC and EC environments, and much research has been directed toward clarifying this question.

2 BIOPHYSICS OF ²³Na NMR

The major difference between Na and ¹H NMR is that Na has spin quantum number $I = \frac{3}{2}$. This means there will be four energy levels, corresponding to the quantum numbers $m = I_z = -\frac{3}{2}, -\frac{1}{2}, \frac{1}{2}, \text{ and } \frac{3}{2}$. Since normal NMR excitation and radiation permits only transitions whose m values differ by 1, there will in general be three possible Larmor frequencies; these are classified as ‘inner’, meaning $\frac{1}{2}$ to $-\frac{1}{2}$, and ‘outer’, meaning either $\frac{3}{2}$ to $\frac{1}{2}$ or $-\frac{1}{2}$ to $-\frac{3}{2}$. If there are no other interactions in the system, the energy levels are equally spaced and the three Larmor frequencies are equal.

However, the Na nucleus also has an electric quadrupole moment, denoted by eQ .¹ (e = electron charge.) This implies that the energy of the nucleus will be influenced by the pre-

sence of an electric field gradient, which is described by a second-rank tensor of strength eq . In this case there is another energy term in the Hamiltonian given by

$$\hat{\mathcal{H}}_Q = \frac{e^2 q Q [3m^2 - I(I+1)] [3 \cos^2(\theta) - 1]}{8I(2I-1)} \quad (1)$$

where θ is the angle between the major axis of the quadrupolar tensor and the z axis. From this Hamiltonian comes a quadrupolar energy E_Q and frequency $\omega_Q = 2\pi E_Q/h$ depending on the quantum state.

Equation (1) has important consequences for the energy levels of the nuclei, the relaxation rates, and signal strength. First, we see that $\hat{\mathcal{H}}_Q$ depends quadratically on m ; this changes the energy level differences of the outer levels but not the inner. Hence the quadrupolar interaction does not change the Larmor frequency corresponding to the inner transition. Both the magnitude and the sign of the energy level shift of the external transitions depend on the angle θ . If the local environment is isotropic, then averaging over angles gives zero average energy displacement. However, in situations of exceptional order (such as liquid crystals) the orientations are not random and a net shifting of the energy levels can occur. The resulting spectrum will show three lines as illustrated in Figure 1. Note that whereas the central line, corresponding to the inner transition, is narrow, the external spectral lines may be broadened by an amount dependent on the details of the microscopic electrostatic environment.

In this situation, quantum theory predicts that only 40% of the total radiated energy will lie in the unshifted inner line, while the remaining 60% may be distributed over the broad outer lines.² Depending on the experimental conditions, it is possible that the outer transitions will be so broadened as to be virtually undetectable with most NMR spectrometers. This leads to the widely discussed phenomenon of ‘NMR invisibility’ of sodium; i.e. several experiments have suggested that the observed Na NMR signal strength is less than what should be observed based on measured Na concentration levels. For example, Shporer and Civan proposed that this would explain previously reported discrepancies between the strength of the Na NMR signal observed and that expected from tissue measurements.³ In particular, they demonstrated this effect for the relatively simple system of sodium linoleate in water.

Figure 1 Schematic diagram of the spectrum from ²³Na in an ordered environment with electric quadrupolar interaction in a first-order approximation. The width of the outer transition lines depends on the strength and correlation time of the quadrupolar interaction. The inner transition carries 40% of the total signal

Joseph and Summers⁴ noted that if the loss of Na NMR visibility were in fact due to a nonoverlapping displacement of the energy levels, then quantum theory predicts that the rate of nutation of the inner (unshifted) spectral component is *twice* that predicted by the usual classical vector model of the NMR excitation. In other words, if an NMR spectrometer is adjusted on a homogeneous phantom (such as aqueous NaCl) so that a particular radiofrequency pulse gives 90° of spin flip, then the same pulse applied to the split Na system will rotate the unsplit component by 180°. They demonstrated the vanishing of the sodium linoleate signal under conditions in which a NaCl phantom gave optimal signal.⁴ This suggests that this 'flip angle effect' could be used to test for the presence of quadrupolar splitting in vivo without the need actually to detect the invisible Na spectral lines. To date, however, no one has demonstrated this effect using realistic in vivo biological material.

The more common interpretation of the quadrupolar interaction is that the orientation angle is isotropically distributed and is rapidly changing with a correlation time, τ_c , on the order of microseconds or less. In this situation the effect of $\hat{H}_Q$ is not to induce energy level splitting but to broaden the lines, i.e., to induce relaxation. The physics of this situation is rather complex.^{2,5,6} The result depends both on whether the product $\omega_0\tau_c$ is large or small compared with unity as well as the product $\omega_Q\tau_c$. If $\omega_0\tau_c \ll 1$, the signal will show only one spectral line. If $\omega_0\tau_c > 1$ (but with $\omega_Q\tau_c \ll 1$) this line may have two distinct decay rates (i.e., two rates for T_1 and two for T_2). The inner and outer transitions give the same spectral frequency but differ in their relaxation rates. The outer transitions produce 60% of the signal and the inner 40%. This phenomenon of biexponential relaxation (BR) is widely observed in nature. For example, most biological tissue shows a short T_2 on the order of a few milliseconds and a longer one on the order of 20–30 ms. These results are interpreted in terms of a correlation time on the order of microseconds. In contrast, the relaxation times of NaCl–water are usually 50 ms or less for both T_1 and T_2 (at 2 tesla); this is due to a very short τ_c on the order of 10^{-11} s.

The phenomenon of BR is related to the question of Na visibility, i.e., if $T_{2f} \ll TE$ then the fast component will have died out before the signal is detected in a spin echo experiment. Obviously, this definition of 'invisibility' is highly dependent on the NMR equipment, and especially the shortest TE used. The use of a pulse spectrometer with very short TE is equivalent to being able to detect a very broad spectral component with a CW spectrometer. Most recent experiments have reported high visibility in biological materials. Joseph and Summers⁴ found essentially 100% visibility in excised cat brain and porcine skeletal muscle. Kohler et al.⁷ found only 80% visibility for Na in the vitreous humor of enucleated eyes, but it increased to 100% after digestion with collagenase.

The actual environment of biological Na ions is considerably more complex than that of a simple solution. Even in the EC space there is always a multitude of proteins, fatty acids, sugars, and other hydrophilic molecules with which the Na ions can interact. One expects short-term 'bonding' and exchange of the Na ions among the various bound and free pools. Such exchange processes are known also to influence the relaxation rates.^{6,8} It is often assumed that the degree of IC Na bonding is much greater than the EC, so that IC Na will

have a shorter T_2 than EC. This conclusion is subject to considerable doubt however, since even homogeneous solutions can produce BR very similar to that seen in vivo. For example, the relatively simple system consisting of NaCl ions in 4% agarose gel shows T_2 values of 5.5 and 23 ms.⁴

Since one motivation for doing Na MRI is the hope of imaging IC versus EC Na, we will review what is currently known about the scientific basis for this. All of this work relies on the use of a hyperfine shift reagent (SR),⁹ such as dysprosium triphosphate (Dy-TTP), which shifts the Larmor frequency of the EC Na only; this means that IC and EC Na have separate spectral lines. Such experiments show that IC Na often displays BR. Shinar and Navon¹⁰ observed BR in red blood cells (RBC) with T_2 values of about 6.6 and 23.6 ms. However, the precision with which one can measure two T_2 components is limited and somewhat dependent on the assumptions made in modeling the decay. For example, Shinar and Navon *assumed* a 40/60 distribution between the slow and fast components (T_{2s}/T_{2f}) as predicted by theory for a single population of spins with BR. From their data one can probably not rule out a somewhat shorter T_{2f} with a different short/fast distribution ratio. Later work by Shinar and Navon¹¹ in the nuclei of chicken RBCs showed T_{2f} values in the 2–8 ms range, where the decay rate had a strong dependence on the IC concentration of DNA.

The BR of the IC Na is only one-half of the question, however. One wants to know if the BR phenomenon is found *only* in the IC Na. In 1986, Shinar and Navon¹² found that none of blood plasma, serum nor various solutions of proteins in water gave BR. This would suggest that the BR phenomenon is limited to IC Na. However, from a detailed analysis of the T_1 and T_2 decay rates they concluded that there was a significant contribution to quadrupolar relaxation from a pool of bound Na even in this noncellular environment. That is, one assumed that the physics of BR was operative but the effect was too weak to be resolvable into two distinct T_2 values. This experiment was done without the use of shift reagents.

Since blood is a relatively small fraction of the fluid in most tissues, one wonders whether the results on blood plasma can be applied to interstitial Na in living tissues. A very careful study of this question was conducted by Foy and Burstein¹³ using Na spectroscopy of perfused hearts in both frog and rat models. They eliminated the contribution of blood by a selective inversion–recovery technique. In part of their experiment they used a shift reagent to distinguish IC from EC Na, with the result that 85% of the signal was EC in this model. They analyzed the transverse decay of the parenchymal signal (i.e., both IC and EC but excluding the blood) without SR and found BR with $T_{2s} \approx 25$ ms and $T_{2f} \approx 2$ ms in both models. Since the fast component was about 40% of the total signal it could not have come solely from the IC compartment. This is clearly a counter example to the hypothesis that short T_2 components are found *only* in the IC compartment of living tissues. However, it is still possible that the *average* IC T_2 could be less than that in the EC space.

Pekar et al. proposed using double quantum (DQ) filtration to distinguish IC from EC sodium.¹⁴ The main point is that DQ, and in general multiple quantum (MQ), signals can emerge only if the physical parameters (strength of the quadrupolar constant and correlation time) are such that BR occurs. Pekar et al. used a SR and found the DQ sodium signal to be

limited to the IC space. This encouraged the hope that IC could be distinguished from EC solely by the physical characteristics of the NMR signal. However, subsequent work by Jelicks and Gupta¹⁵ demonstrated that the presence of the SR in the EC would itself quench an MQ NMR signal. This means that the absence of EC MQ signal as observed by Pekar et al. did not contradict the finding of Foy and Burstein that BR does occur in the EC space. However, by detecting an MQ signal in the presence of SR it does provide an alternative method for obtaining a pure IC signal.^{16,17}

3 IMAGING TECHNIQUES

The principles of imaging sodium do not differ from those used to image protons; basically, in addition to exciting the Na spins and reading out the signal, some means must be provided for spatial encoding.¹⁸ The main differences are due to the characteristics of the Na signal already discussed, namely, the low S/N and the short values of T_1 and T_2 . Short T_1 , on the order of 50 ms in tissue, is an advantage since it implies rapid recovery of longitudinal magnetization after excitation so that short TR values can be used with little loss of signal. The low S/N forces one to employ techniques with relatively poor spatial resolution and long imaging times; typical values are 3×3 mm in-plane resolution and 10 mm slice thickness. Imaging times are usually a large fraction of 1 h.

The most important aspect of Na imaging is the need to achieve short echo times. One wants quantitation of the short versus long T_2 components, and the goal of imaging is to demonstrate these differences anatomically. A common technique is to use gradient echo (GE), which is equivalent to imaging the free induction decay (FID). The fact that GE is more sensitive than spin echo (SE) to background field gradients is rarely of importance for sodium, partly because the low γ implies less sensitivity of phase shift to the background fields and partly because the TE values achieved are usually less than 3 ms.

There are several ways in which spatial encoding can be applied. The single slice two-dimensional Fourier transform (2DFT) technique widely used in proton images can be used. More commonly, however, for multislice imaging, three-dimensional Fourier transform (3DFT) is used (Figure 2). The initial excitation may be a hard, nonselective pulse or a 'slab' which consists of a set of slices to be imaged. The slice definition is obtained by phase encoding the z axis. To reduce aliasing one can saturate spins outside of the desired region.¹⁹ As shown in Figure 2, it is possible to obtain both a FID and SE signals. Some workers have employed a prephasing G_x pulse during the phase-encoding interval so that the $k_x = 0$ echo is delayed; this is called a GE. The advantage of the GE is that both positive and negative k_x values are obtained in the same data acquisition (DA), which leads to fewer imaging artifacts due to background gradients, eddy currents, etc. However, the resulting delay in the minimum echo time is disadvantageous for detecting the short T_2 component.

Both of the FT techniques require the use of phase-encoding gradient pulses applied after excitation and before signal read out. This is a major disadvantage because they delay the time at which signal acquisition can begin and will therefore severely attenuate the short T_2 component. A technique that

Figure 2 Pulse sequence diagram for 3DFT with both a FID and a spin echo (SE) detected. The 90° pulse is meant to excite a slab of slices in the z direction. The dotted lines on the G_z and G_y pulses indicate phase encoding which varies from one excitation to another (ZPE, z phase encoding; YPE, y phase encoding)

avoids that delay is projection–reconstruction imaging (PRI). PRI works by reconstructing an object from measurements of its projections along many lines or planes over a wide range of angles. The two dimensional (2D) form of PRI is the basis of all clinical X-ray computerized tomography (CT) scanners, and was also the first technique used for MRI.²⁰ Shepp²¹ showed how the 2D PRI method could be generalized to three dimensions. In this method, whose pulse sequence is illustrated in Figure 3, each excitation is completely nonselective and is followed immediately by readout of signal in the presence of all three gradients. The signal $S(t)$ will be the Fourier transform of the spin density along the direction defined by the gradient vector, $\mathbf{g}$:

$$S(t) = \iiint M(x, y, z) \exp(i\gamma \mathbf{g} \cdot \mathbf{r}t) dx dy dz \quad (2)$$

where $\mathbf{r} = (x, y, z)$ is the position vector and $M(x, y, z)$ is the spin density at point $\mathbf{r}$, weighted by the relevant relaxation factor. If we can neglect T_2 decay during the readout period, Fourier transform of the signal yields a frequency distribution $S_f(\omega)$ given by

$$S_f(\omega) = \int S(t) \exp(-i\omega t) dt = \iiint M(x, y, z) \delta(\omega - \gamma \mathbf{g} \cdot \mathbf{r}) dx dy dz \quad (3)$$

where $\delta()$ is the Dirac delta function. Equation (3) indicates that the signal corresponding to any given frequency ω comes from a plane perpendicular to the $\mathbf{g}$ vector and displaced by

Figure 3 Pulse sequence diagram for 3D PRI. The 90° pulse is hard. The relative magnitudes of the G_x , G_y , and G_z pulses are varied from pulse to pulse such that the gradient vector sweeps over a spherical surface in k -space

distance $\omega/(\gamma g)$ from the origin. To reconstruct the density $M(x, y, z)$ it is necessary to collect a set of signals in which the gradient vector ranges, more or less uniformly, over the full range of the 4π solid angle of a sphere.²² In the language of k -space, each gradient vector defines a vector in three-dimensional (3D) k -space, which varies with time t as

$$\mathbf{k}(t) = \int \gamma \mathbf{g} \, dt = \gamma t \mathbf{g} \quad (\text{for } \mathbf{g} = \text{const}) \quad (4)$$

Hence, the 3D PRI method essentially scans k -space along a series of spokes starting from the origin and extending out to some maximum value. To reconstruct the function $M(x, y, z)$ the data in k -space are first multiplied by the factor k^2 then Fourier transformed back to the image domain to yield a set of modified planar data.²³ These planar ('filtered') data are then directly projected onto the 3D image matrix. The method is easily generalized to include multiple spin echoes.²⁴

The major advantage of 3D PRI for Na MRI is that data acquisition can begin immediately after excitation, without the need to wait for gradient pulses to play out. This is especially advantageous when eddy currents and gradient amplifier limitations add ≈ 1 ms to the nominal time duration of gradient pulses. The method is intrinsically three dimensional, so one is committed to a rather large number of pulses to sample k -space adequately. However, like 3DFT, the method is very efficient for signal to noise ratio (S/N) because each excitation includes the entire volume imaged. However, the method is sensitive to frequency offset and B_0 inhomogeneity errors, but for Na MRI these are rarely a significant problem.

This method has no dephasing gradient prior to signal read-out; this means that on any excitation only one-half of the k region is covered; i.e. $k > 0$ on one excitation and $k < 0$ on another. This technique is called 'half echo', and results in the

earliest possible time for the $k = 0$ part of phase space. However, if T_{2f} is much less than the DA time window, high k values will be attenuated and the image will suffer loss of spatial resolution. This is a consequence of imaging objects with very short T_2 using frequency encoding.

An interesting variant of this technique combines Fourier encoding in the slice direction with PRI in the transverse plane; a Hahn SE time of 3.6 ms has been obtained on a clinical MRI machine.²⁵

Another approach to the problem of achieving rapid data acquisition after excitation is to use gradients in the rf B_1 field. This method has been applied to Na MRI, but the image quality obtained was less than that obtained by workers using the more conventional B_0 gradient methods.²⁶

When shift reagents are used, it is necessary somehow to image separately the two spectral lines produced. This can be done using various methods well known from proton chemical shift imaging.²⁷ For example, Kohler et al.²⁸ used a 2D phase-encoding technique equivalent to that originally proposed by Brown et al.²⁹ This technique uses a standard spatially selective excitation produced by the application of the z gradient, followed by phase encoding in both the x and y planes. The signal is read out in the absence of a gradient, so that Fourier transform will yield the spectrum. This sequence commits the experimenter to a relatively large number of excitations ($N_x \cdot N_y$). However, for Na imaging this is not a problem since one is usually forced to use a long scan time to achieve acceptable S/N. This technique can be generalized to use multiple echoes (on the long T_2 component) and a matched filter can be used to optimize S/N.³⁰

The previous techniques are classed as single quantum (SQ). There is interest in obtaining MQ signals and using them for imaging. Wimperis and co-workers have investigated this, and the details are discussed elsewhere.³¹ Triple quantum (TQ) is a better choice than DQ for this purpose. The minimum pulse sequence to generate MQ coherence consists of three rf pulses: $\alpha_1-t_1-\alpha_2-t_2-\alpha_3-t_3$ -DA, where the optimal values for the flip angles α_i depend on the type of experiment, and the optimal interpulse time intervals t_i depend on the relaxation properties of the Na. This pulse sequence gives a mixture of coherence orders, and it is necessary to 'filter' the signal to obtain the desired coherence. This is done by cycling the phase (ϕ in Figure 4) of the last rf pulse; the choice of flip angle $= 109^\circ$ maximizes the TQ signal component for this sequence.³²

The simplest technique for MQ MRI is simply to append one of the previous SQ imaging pulse sequences to the previous MQ preparation sequence. However, a more ingenious imaging pulse sequence has been suggested by Wimperis and Wood³¹ which uses the unique properties of the TQ coherence to select the TQ signal without phase cycling. The pulse sequence is shown in Figure 4. The first 90-180-90 set of pulses refocuses dephasing due to B_0 inhomogeneity and/or chemical shift effects. During time interval t_2 there is TQ coherence. This implies that the phases of the relevant matrix elements evolve at three times the SQ Larmor frequency. Thus, the gradient pulses applied during that time need only be one-third as strong (or long) as in SQ techniques. This is an advantage in systems whose gradients are designed for proton imaging and in which it is difficult to achieve the factor of four increase needed to obtain high-resolution Na images. Furthermore, the TQ signal decays during that time at a rate

Figure 4 Pulse sequence diagram for triple quantum Na imaging. The dotted lines for the G_z and G_y pulses indicate phase encoding (PE). The x axis is frequency encoded during the data acquisition period (DA)

comparable to T_{2s} , so there is less need to minimize the time duration.³¹ Application of the frequency-encoding prephasing pulse (on G_x) during this time sets up a typical echo during the readout time as shown. However, in this case the area under the prephase pulse needs to be only one-third that of the readout gradient pulse; this unusual condition acts to select only the TQ desired coherence component so that phase cycling is in principle not necessary. (However, in practice the SQ signals are so strongly excited that phase cycling is recommended.) The strength of the TQ signal developed, S , depends on both t_1 and t_3 according to the function

$$S(t_1, t_3) \propto f(t_1)f(t_3) \quad (5)$$

where

$$f(t) = \exp(-t/T_{2s}) - \exp(-t/T_{2f}) \quad (6)$$

When $T_{2s} \gg T_{2f}$, $f(t)$ starts at zero, builds to a maximum in time $\approx T_{2f}$, and decays with time constant T_{2s} . Hence it is not necessary to achieve ultrashort echo or DA times with this sequence.

The drawback to MQ imaging is the reduction in signal amplitude relative to SQ.¹⁵ In particular, the use of gradients to filter the MQ coherence reduces signal by a factor of two.³² Wimperis et al.³³ have modified the technique in an attempt to increase S/N. However, they demonstrated only modest image quality in a phantom of 200 mM Na, which is 10 times the amount present IC. Keltner et al.³⁴ have used a technique similar to Figure 4 to image a phantom containing 12 mM Na, obtaining an excellent S/N in voxels of $1.5 \times 1.5 \times 1.5$ cm size. To date, no one has published in vivo MQ images of Na with an image quality acceptable for biological application.

4 BIOLOGICAL APPLICATIONS

To date, most applications of Na MRI to biomedical problems have been experimental. These applications can

be roughly categorized as concerning edema, infarction, and neoplasia.

4.1 Imaging Studies of Edema

Edema means the pathological increase in water content of tissues. When the edema is due to leaking blood vessels, the excess water is EC and its Na content should be about 150 mM, i.e., much greater than the IC level. This will result in increased Na signal. Furthermore, since the IC [Na] is so low, the amount of signal increase will largely reflect the increase in the size of the EC space. However, these same factors lead to increased signal in conventional T_2 -weighted proton images, so Na MRI has not found widespread use as a clinical tool for this purpose.

One application of this principle was described by Lancaster et al.³⁵ who imaged experimental lung edema in rats. Proton MRI is especially problematic in this case because of severe suppression of signal due to the inhomogeneous magnetic susceptibility of normal lung tissue. Sodium MRI is less sensitive to this effect because of its reduced γ . They demonstrated much more dramatic increases in Na signal than proton signal in their model of permeability edema. They also attempted to isolate the vascular component of Na by using an iron oxide superparamagnetic particle suspension to suppress the vascular Na.

4.2 Imaging of Stroke and Infarction

The rationale for this application is that if a cell dies, its Na-K pump will shut down and the IC [Na] will increase. However, to demonstrate the effect experimentally sometimes involves reperfusing the organ following vascular occlusion in order to provide a source of the excess Na. Working with such a dog heart model, Cannon et al.³⁶ demonstrated increased Na signals in regions of ischemic damage. Some early work by Hilal et al.³⁷ demonstrated increased Na signal in MRI of the brain in one patient; both an old and a recent (2 h) stroke were shown. However, visualization of old strokes is easily accomplished with T_2 -weighted proton MRI. The demonstration of early stroke would be very valuable clinically if it could be accomplished in a rapid and routine fashion. There has been little subsequent work in this area, and current research on MRI of stroke is more focused on the possible utility of diffusion-weighted proton MRI.

4.3 Imaging Studies of Cancer

There is much work in the area of distinguishing IC Na levels in normal and malignant cells. For example, Liebling and Gupta³⁸ found that IC Na of a benign uterine leiomyoma was relatively depressed at only 5.1 mM, while a malignant leiomyosarcoma had the elevated value of 34.6 mM. There have been many in vitro nonimaging studies of tumors in animal models which will not be reviewed here. Imaging is useful when it is desirable to see the spatial distribution of Na in more detail. Summers et al.³⁹ used Na MRI to study the development of necrosis in an animal model of human neuroblastoma; they found that the total Na signal (not distinguishing IC from EC) tended to rise with increasing tumor necrosis. Lin et al.⁴⁰ used Na MRI to distinguish two different

grades of tumor in a rat prostate tumor model; they found the two differed in the magnitude of T_{2s} in a way that could not be seen using proton MRI.

Several groups have demonstrated increased Na signal in human brain cancer. However, since most tumors are visualized using proton MRI, the interest is whether Na MRI can make more specific diagnoses. In some cases, the technique uses a relatively short gradient echo as well as several spin echoes with longer TE . In the normal brain, if $TE > 10$ ms the only structures visible are those containing cerebrospinal fluid and the vitreous humor of the eye. Looking only at echo times greater than 13 ms, Turski et al.⁴¹ found that a brain stem glioma showed less enhancement than an astrocytoma in the pons. Hashimoto et al.⁴² used a short TE (1.9 ms) gradient echo as well as longer spin echoes. However, they reported that the most useful differences between the Na and proton images of a meningioma were derived from the long TE images; the short TE images were obviously blurred. Schuierer et al.⁴³ looked at a variety of supratentorial lesions with Na MRI at 4.0 tesla using only a $TE = 11$ ms echo; they found that Na MRI did not contribute any information that was not provided by proton MRI or X-ray CT.

Hilal and co-workers⁴⁴ have energetically applied Na MRI to brain cancer. Skirting the recognized difficulties in differentiating IC from EC Na, they derive an image of 'putative intracellular' Na from a gradient echo starting at $TE = 0.2$ ms and two spin echoes ($TE = 12$ and 24 ms). The long T_2 signal, assumed to be purely EC, is used to estimate the EC volume fraction by comparison with the vitreous humor. The short T_2 component is computed by subtracting the value of the EC signal extrapolated to $TE = 0$ (equivalent to what is called 'curve stripping'). From these numbers an estimate of the putative IC concentration $\{[Na]/(IC \text{ volume})\}$ is obtained for each pixel in the image. From their preliminary sample of 23 patients, they found a correlation between the IC [Na] and the histological grade of gliomas and astrocytomas. Like Hashimoto et al., they also found that Na MRI often reveals a larger tumor than proton MRI.

Thus, there is ample evidence that Na levels are increased in various types of tumor. However, whether this is due to increases in the IC or EC space is a complex question, and the answer probably will depend on the type of tumor and which organ it is in. In particular, many tumors have a loosely organized cellular system and so have a relatively large EC space compared with normal tissues. In these cases, the increase in EC Na would probably correlate with the signal increase seen in proton MRI.

1 SUMMARY

Recently, developments in magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), and functional magnetic resonance imaging (fMRI) have opened up new opportunities for the noninvasive investigation of the brain. In epilepsy, these noninvasive techniques play a major role in the clinical investigation of patients with epilepsy.

MRI can noninvasively detect virtually all foreign tissue lesions (tumors) such as hamartomas, gliomas, oligodendrocytomas, dysembryoplastic neuroepithelial tumors and other developmental lesions. It has been able to define these lesions with a great deal of anatomical accuracy. This in itself is a tremendous advance which can now easily be taken for granted. Perhaps even more impressive has been the ability of optimized structural imaging techniques to detect smaller abnormalities of gray matter, in particular lesions like subtle cortical dysplasias, minor abnormalities of gray matter, and especially hippocampal sclerosis. In the important lesion of hippocampal sclerosis, quantitative measures of both the abnormal morphology (volume) and abnormal signal (T_2 relaxation measurement) have allowed this diagnosis to be made objectively. The clinical impact of this noninvasive information cannot be overstated. A major challenge now is to be able to reliably detect subtle areas of dysgenesis in the cortical gray matter.

MR spectroscopy provides information about brain metabolites that appears to provide objective information about regional damage in the temporal lobe which is not readily apparent with conventional imaging. Both these methods have enabled the detection of bilateral temporal lobe abnormalities, and the consequences of this bilateral damage on cognitive and seizure outcome is being explored. These techniques show fixed brain pathology. With the development of functional MRI it is possible to see signal change associated with activated neurons. As well as detecting normal activation (such as hand movement), it has been possible to image seizures. This gives information about both the spatial and the temporal location of signal changes during seizures. It appears that interictal activations may also be detectable.

This abundance of new MR techniques that allows so many aspects of brain structure, function and biochemistry to be investigated in the clinical setting has revolutionized the ability to detect brain abnormalities which underlie the epilepsy condition. In surgical programs for the treatment of epilepsy, MR has become at least as important as the EEG. The information from MR will have a major impact on the classification and understanding of epilepsy syndromes.

2 EPILEPSY, THE CLINICAL PROBLEM

Epilepsy is a common problem occurring in up to 1% of the population.^{1,2} Intractable epilepsy which is a debilitating disorder may occur in up to 0.25% of the population. It is an extremely important neurological condition because there are severe social and medical consequences of the disorder^{3,4} (up to 1% of patients die per year and many more are severely affected). Individuals otherwise often have the capacity to live normal lives, and complete cure is possible in a large number of these if a seizure focus exists, can be identified, and can be surgically removed.

Epilepsy is a disorder predominantly of the gray matter. This includes a wide variety of pathologies such as tumors (some of which may be small), subtle lesions such as cortical dysplasia, and often minor abnormalities of development of subtle degrees of brain injury such as hippocampal sclerosis or cortical gliosis. The predominant abnormality in these patients varies from the macroscopic to the cellular level, and may be characterized by predominantly biochemical or metabolic abnormalities.

3 CLASSIFICATION OF EPILEPSY CONDITIONS

In general terms epilepsy can be divided into two main groups: generalized and partial epilepsy.⁵ In generalized epilepsy the seizure arises almost simultaneously in all parts of the brain. In partial epilepsy, by comparison, the seizure begins in one distinct part of the brain, and may then spread to other parts of the brain. There is an implication that generalized epilepsy involves an abnormality in multiple, or all, parts of the brain, while partial epilepsy implies that the abnormality is confined to a limited portion of the brain. The international classification which is most widely accepted⁶ further divides the epilepsy conditions into those that are 'symptomatic' (that is have a defined pathological cause such as a tumor) and those that are 'idiopathic' (have no defined lesional cause). The recent development of MR tools for the investigation of brain structure, biochemistry, and function have had a major impact on the thinking in clinical epilepsy. The ability to define lesions (such as hippocampal sclerosis and cortical dysplasia), which were previously 'cryptogenic' and only detectable when pathological studies had been performed, means that the classification and principles upon which clinical epilepsy is based are undergoing major revision at the present time as a direct consequence of the information provided by MR studies.

4 THE CHALLENGE FOR MR STUDIES: THE INFORMATION THAT IS SOUGHT IN EPILEPSY PATIENTS

The problem of epilepsy necessitates understanding of brain structure, function, and biochemistry in normal and pathological states. The central problems in the understanding and management of intractable epilepsy are as follows.

1. To determine whether the epilepsy syndrome is generalized (no defined site of seizure onset, i.e. onset almost simultaneous in all or many parts of the brain) or partial (focal or localized seizure onset, with or without subsequent generalized spread).
2. To define whether a structural abnormality of the brain exists which may give rise to the epilepsy disorder (if so, known as symptomatic epilepsy; if not, then defined as idiopathic epilepsy).
3. If partial, to define the location, and extent, of the region (or regions) responsible for the generation of the seizures, and how functional events relate to underlying structural abnormality.
4. To understand which lesions are epileptogenic, and what abnormalities of structure and function define such areas.
5. To determine the effects of seizures on the brain. Do seizures cause damage (e.g. cellular damage, neuronal loss, hippocampal sclerosis) or is it the disease or condition that gives rise to the epilepsy disorder which causes all of the damage to the brain?
6. To identify important functional areas of cortex (movement, speech, memory) which must be preserved if a neurosurgical procedure is to be performed for treatment of intractable seizures.

Therefore, noninvasive investigations contribute to the solution of these problems by identifying gray matter lesions such as hippocampal sclerosis, replacing the use of invasive methods used to localize the site of seizure origin, defining the nature and extent of the structural, functional and metabolic abnormalities of the seizure focus, and determining preoperatively factors which influence the likely seizure and functional outcome from surgical treatment.

5 STRUCTURAL ABNORMALITIES SHOWN BY MR IMAGING

5.1 Tumors

Approximately 20% of all patients with intractable epilepsy will have a relatively large lesion (tumor) as the basis of their

epilepsy. Before MRI only about 50% of these lesions were detected preoperatively (with CT) when located in the temporal lobes.⁷ As these patients generally have an excellent outcome after surgery it is essential to identify them. Many series have now established that MR detects virtually all tumors, including dysembryoblastic lesions, hamartomas, and gliomas.

5.2 Hippocampal Sclerosis

Hippocampal sclerosis is one of the most common lesions found in the brains of patients with intractable epilepsy.⁸⁻¹⁰ It is important for several reasons. It is a highly epileptogenic lesion. The side of the most affected hippocampus is almost always the side from which the majority of temporal lobe seizures originate. The detection of hippocampal sclerosis by MRI may obviate the need for invasive EEG monitoring with its attendant morbidity in patients being considered for surgery. Until new MR techniques arose, hippocampal sclerosis was considered as nonlesional epilepsy: the reliable detection of hippocampal sclerosis changes the clinical perspective of these patients.

The first reports of the MR detection of hippocampal sclerosis were rather confusing with encouraging results reported in some small studies, confusion with artifacts in others, and inadequate pathological verification in many. There were even studies that failed to detect any abnormality. In 1987, Kuzniecky and colleagues, from the Montreal Neurologic Institute, published the first major series of papers in which hippocampal sclerosis was detected in a systematic way, and shown to be related to pathological findings.¹¹ This study relied almost entirely on T_2 -weighted signal changes. Using optimally oriented imaging planes, and heavily T_1 -weighted inversion recovery sequences in addition to T_2 -weighted sequences, hippocampal sclerosis was shown to be reliably detected by visual inspection of images acquired at 0.3 tesla using the criteria of hippocampal atrophy and T_2 -weighted signal change in hippocampal gray matter.^{7,12} Since then optimized imaging at 1.5 tesla has shown that there are four main features of hippocampal sclerosis visible in MRI^{13,14} (Table 1).

The criteria for assessing these optimized images include both morphological and signal intensity changes. The morphological features are atrophy and disruption of internal hippocampal structure. Abnormal signal in the hippocampus can be seen on both inversion-recovery (T_1) and T_2 -weighted imaging. The imaging of the fine anatomical structure of the hippocampus, to a level of detail previously possible only with microscopic examination (Figure 1 shows details of this) may become an even more important method of detecting hippocampal sclerosis with improvements in imaging resolution.

Table 1 Features of hippocampal sclerosis

MRI feature of hippocampal sclerosis	Suggested histopathological correlate of the MR imaging abnormality
• Unilateral atrophy (right cf. left) • Loss of internal morphological structure on IR images • Increased signal on T_2-weighted images • Decreased signal on T_1-weighted images (IR)	• hippocampal atrophy • loss of neurones in CA1, CA2, and CA4 and replacement gliosis [Figure 6(d)] • gliosis • gliosis

Figure 1 The features of hippocampal sclerosis on optimized imaging are shown here in the imaging plane which transects the hippocampus at right angles (a). These images show atrophy, and reduced T_1 signal (b) and increased T_2 signal (c)

5.3 Visual Analysis of the Hippocampus

The visual diagnosis of hippocampal sclerosis can be highly subjective, and even experienced neuroradiologists may have difficulty detecting this subtle lesion. It must be emphasized that not all features are seen in all cases. Unequivocal signal change (as long as the hippocampus is not enlarged) or atrophy may be accepted as diagnostic of hippocampal sclerosis, with the certainty increased if both are present. The addition of internal structure loss can be very helpful if the abnormality is subtle. Several series which compare blinded visual reports to pathological material have shown beyond doubt that hippocampal sclerosis can be reliably diagnosed by visual analysis. In

experienced hands, and with optimized images, high sensitivity and specificity can be achieved. In order to do this optimized images must be performed¹³ and all features of hippocampal sclerosis must be appreciated and searched for. It is our experience that no single feature (such as atrophy) on its own is sensitive enough for reliable routine visual diagnosis, although some expert centers achieve an accurate diagnosis in about 80% of cases.^{15,16}

5.3.1 Atrophy

The assessment of the cross-sectional size of the hippocampus must be made in images obtained in the modified (tilted) coronal axis that transects the hippocampus at right

Figure 2 Internal structure of the hippocampus as seen on optimized MR images [normal (a),(b), hippocampal sclerosis(c),(d)]

angles. A smaller hippocampus as detected in this plane either qualitatively, or by quantitative methods, reliably predicts the side of the epileptogenic focus in the case of temporal lobe epilepsy but absolute measures of hippocampal size must be interpreted with caution.¹⁷ Quantitation of atrophy (hippocampal volume measurement) is slightly more sensitive than visual assessment of hippocampal size. But with the addition of other visual features of hippocampal sclerosis this difference is less marked, or even reversed.

5.3.2 Loss of the Normal Internal Morphological Structure of the Hippocampus

Normal internal morphological structure of the hippocampus is produced by the alveus, the molecular cell layer of the dentate gyrus, and the pyramidal cell layer of the cornu ammonis, and can be seen on optimized coronal MR images [Figure 2(a) and (b)]. In hippocampal sclerosis, the loss of this normal internal structure is a consequence of neuronal cell loss and replacement of normal anatomical layers with gliotic tissue [Figure 2(c) and (d)]. This feature of hippocampal sclerosis is potentially very important as, with increasing spatial resolution, thinning of the CA1 region of the cornu ammonis may prove to be the most sensitive and specific means of diagnosing hippocampal sclerosis. Attempts have been made to define this with specially designed coils; however, increased resolution

which will routinely show this microanatomy is becoming possible using standard equipment.

5.3.3 Signal Hyperintensity on T_2 -Weighted Images

Increased T_2 -weighted signal when localized imprecisely to the 'mesial temporal region' may be due to foreign tissue such as a glioma or hamartoma, to gliotic tissue in the hippocampus, to increased cerebrospinal fluid in the atrophied region, to flow artifacts and occasionally from a developmental cyst in the hippocampal head stemming from failure of closure of the lateral aspect of the hippocampal fissure. Careful determination of the exact location of this signal change by detailed examination of the anatomical features enables the correct diagnosis to be made. It is important to have sufficient knowledge of both the hippocampal anatomy and the easily recognizable artifacts that can occur in this region so that artifacts are not confused with significant signal abnormalities in the hippocampal gray matter.

5.3.4 Signal Hypointensity on T_1 -Weighted IR Images

At 1.5 tesla, using a TR of 3500 and a TI of 300 ms, a sclerotic hippocampus appears small and dark, and the internal features are obscured (Figure 1). The presence of three features in a single coronal image makes the visual diagnosis of hippo-

Table 2 340 Patients, pathological verification of MRI diagnosis in 149

MRI diagnosis	%	Number/location
Hippocampal sclerosis	57	194
Foreign tissue lesion (glioma, astrocytoma or dysembryoplastic tumor)	13.5	46 (36 temporal, 10 extratemporal)
Cortical dysplasia	10.5	35 (12 temporal, 23 extratemporal)
Vascular malformations (12 cavernous hemangiomas, two high flow lesions)	4	14 (6 temporal, 8 extratemporal)
Cystic lesions	1.5	5 (4 temporal, 1 extratemporal)
Miscellaneous	5	17 (5 trauma, 1 tuberous sclerosis, 2 epidermoid, 4 extensive white matter lesions, 1 cerebellar atrophy, 4 uncertain)
No lesion demonstrated	8.5	29
Total	100	340

campal sclerosis much easier, and makes it possible to detect mild degrees of abnormality.

An abnormal signal on T_1 - or T_2 -weighted images arising from an atrophic hippocampus almost always represents hippocampal sclerosis. An abnormal signal arising from an apparently enlarged hippocampus may represent a hamartoma or glioma. If one relied only on a single feature such as atrophy, then these cases of the larger hippocampus being abnormal would be incorrectly lateralized.

5.4 Visual Analysis: Findings Other than Hippocampal Sclerosis

Detailed analysis of MRI images reveals a high percentage of abnormalities which can be detected in the brains of patients with intractable partial epilepsy. As MR techniques improve, it is becoming clear that most patients with intractable epilepsy have detectable imaging abnormalities. Table 2 shows the range of abnormalities which were detected in a combined series of patients from several centers. While often, in the past, no cause could be identified for many cases of intractable partial epilepsy, it is now becoming clear that most adults and children with partial epilepsy will have defined brain abnormalities visualized on appropriate optimized imaging.^{7,13,16,18–26}

6 QUANTITATIVE DIAGNOSIS OF HIPPOCAMPAL SCLEROSIS

There has been a widespread problem in achieving the best results using visual analysis (and routine reporting of MR studies) in the clinical environment. It is clear that the results of visual inspection can be replicated in different centers, and that the findings are specific and sensitive when optimized images are interpreted in expert hands. It is equally clear that this expertise is hard to come by. This is probably because the lesion of hippocampal sclerosis differs from a normal hippocampus by a degree that might have previously been attributed to artifact or normal variation. Therefore considerable experience is required to gain expertise in this diagnosis. For this reason, for research purposes, and for the detection of abnormalities beyond the sensitivity of the eye, quantitative diagnosis of hippocampal abnormalities has been essential. The features

of hippocampal sclerosis are the same as when assessed visually. Much initial attention has been given to the quantitation of hippocampal atrophy but quantitation of signal characteristics is also possible.

6.1 Volumetric Analysis

In 1990 Jack and co-workers^{17,27,28} published their method of quantifying hippocampal atrophy which for the first time enabled an objective measurement of hippocampal pathology. The use of volumetric measurement to assess hippocampal size had been successfully adopted (and adapted) by many centers.^{7,13,16,22–26,29–33} Despite different protocols, this has proven to be a reliable means of determining the lateralization of hippocampal pathology in up to 90% of cases with hippocampal sclerosis. It is our impression that visual analysis in the most expert centers detects virtually all cases that are detected by volumetric analysis, although volume techniques are more sensitive than visual analysis for the detection of the single feature of hippocampal atrophy. There are some cases, because features in addition to atrophy are considered, which can be detected by visual analysis and not by volumetric analysis.³⁴ Because of the range of normal variation, and measurement error, the most reliable use of the volume measurement technique (and indeed visual analysis) has been in lateralization. It has not been easy to determine bilateral hippocampal abnormalities or to determine abnormality without comparison between sides. The strength of the volumetric technique is that the anterior–posterior distribution of the atrophy can be determined³⁵ and the quantitative analysis removes the sometimes subjective nature of the analysis. The greatest weakness is that the only well verified and reliable technique (because of normal variation) is the use of side to side ratios. This means that bilateral disease is not usually detectable.

6.2 T_2 Relaxometry

As well as quantifying the hippocampal atrophy, one can quantify the T_2 signal in the hippocampus by measuring the T_2 relaxation time in the hippocampal gray matter (Figure 3).³⁶ The T_2 relaxation time can be measured quantitatively by measuring the decay in signal intensity at different echo times in a series of T_2 -weighted images acquired in the same slice.

Figure 3 The T_2 map (a) is constructed from the T_2 relaxation times measured for each pixel. The relaxation time is presented as intensity, and can be measured directly for any region of interest (shown for the hippocampus). The histogram (b) shows the distribution of measured T_2 relaxation times in those patients with hippocampal sclerosis (labeled ipsilateral and contralateral to the side of seizure onset) and controls

Each pixel of the resulting T_2 map is derived from the intensity in each of 16 images in that same slice.

This objective measurement has a small range of values in normal subjects. The T_2 relaxation time appears to be very pre-

cise in normal tissue. This enables the detection of pathology without requiring comparison between two hippocampi. Therefore, as well as being sensitive, it permits the detection of pathology in the contralateral hippocampus.

In our experience, the T_2 relaxation time within the hippocampus is a robust and reliable objective measurement of hippocampal pathology, providing a means of assessing the hippocampus which is as good as our most skilled visual interpretation of hippocampal abnormality in optimized scans. In contrast to both visual interpretation and volumetric analysis of hippocampal atrophy, the definition of a normal hippocampal T_2 relaxation time is very precise. Therefore, T_2 quantification has the ability to detect very mild, bilateral and progressive hippocampal abnormalities. Moreover, T_2 values can be interpreted in terms of hippocampal pathology even when the other hippocampus is incomplete or distorted, such as when a lesion is present or following temporal lobe surgery. In these difficult cases, pathology of the residual ipsilateral hippocampus and the contralateral hippocampus may still be diagnosed. It has recently been shown that there is a very close correlation between hippocampal atrophy, hippocampal T_2 abnormality and pathological findings. Therefore, findings from hippocampal volume studies (such as outcome, and pathology correlations) should apply to T_2 abnormalities, while the latter has the advantage of detecting bilateral disease.

7 MR SPECTROSCOPY

As discussed elsewhere in this volume, several lines of evidence suggest that almost all the *N*-acetylaspartate (NAA) within the brain is neuronal,^{37–40} and so a reduction in the NAA signal is commonly interpreted in terms of neuronal loss or damage. Such a case is shown for the temporal lobe in Figure 4. Here the NAA signal is reduced and the signals from choline containing compounds (Cho) and creatine + phosphocreatine (Cr) are increased. While interest focuses on the NAA signal as a marker of neuronal damage or loss, it is often impractical to quantitate this as an absolute quantity. Usually a marker of abnormality is being sought, so the ratio of NAA to Cho or Cr is often used as such a marker. In the temporal lobe it may often be difficult to resolve the Cho and Cr signals unequivocally, therefore we recommend that the ratio $\text{NAA}/(\text{Cho} + \text{Cr})$ is an appropriate marker of pathology for clinical use.

MR spectroscopy studies have shown overall abnormalities in the NAA, Cr and Cho signals in the temporal lobes of patients with well localized intractable temporal lobe epilepsy.^{41,42} In comparison with controls, the temporal lobes ipsilateral to the seizure focus show a 22% reduction in NAA signal intensity, a 15% increase in the Cr signal, and a 25% increase in the Cho signal. The NAA change is interpreted in terms of neuronal loss (or damage). The interpretation of the increase in Cho and Cr signals is not yet clearly defined. However, studies of neural cells show that the concentrations of choline-containing compounds and of creatine + phosphocreatine are much higher in astrocyte and oligodendrocyte preparations than in cerebellar granule neurons.³⁷ Thus, increases in Cr and Cho may reflect reactive astrogliosis suggesting that both neuronal loss and astrogliosis may be identified by the noninvasive measurement of metabolites by MRS.^{37,43–45}

Figure 4 Spectra from (a) the temporal lobe contralateral to the seizure focus in a patient with temporal lobe epilepsy and (b) from the ipsilateral temporal lobe. Note the decrease in NAA in the ipsilateral temporal lobe

Using the ratio $NAA/(Cho + Cr)$, MRS has been used to lateralize up to 70 patients with intractable temporal lobe epilepsy. In about 40 of these cases the abnormality was bilateral, and like T_2 relaxation time measurements could be used to detect bilateral abnormalities. MRS is sensitive to bilateral and diffuse pathology and it is an objective measure of metabolite abnormalities which cannot be visualized directly with MR

imaging. We view these MR spectroscopic abnormalities as a marker of regional abnormalities of the temporal lobe in these patients. We do not believe that it is a marker simply of hippocampal sclerosis, but it provides additional information about pathology of the temporal lobes which is not available by other MR methods.

Chemical shift imaging (CSI) or magnetic resonance spectroscopic imaging has the advantages of being able to determine the regional distribution of metabolites and to identify areas of maximal abnormality. In a study of ten patients with temporal lobe epilepsy and five controls the left-right asymmetry of NAA/Cr ratios was found to be significantly different from controls in all cases.⁴⁶ The use of such an asymmetry index alone precludes the detection of bilateral abnormalities. However, comparison of NAA/Cr ratios in patients and controls indicated that two patients had bilateral reduction in the NAA/Cr ratio in the posterior temporal region, and the greatest reduction was ipsilateral to the maximum EEG disturbance. A further CSI study, using a 2T Philips system with a 4 mL effective voxel size, was performed on eight patients with unilateral complex partial seizures and eight controls.⁴⁷ Significant asymmetry in the intensity of the NAA signal was found in all patients. In each case the lower NAA corresponded to the side of seizure focus as determined by EEG. No significant changes in Cho or Cr were observed.

It is apparent that CSI has distinct advantages over single voxel techniques in terms of coverage of the brain, and it is becoming the method of choice in a number of centers for the study of epilepsy. However, it is technically more demanding than single voxel MRS, particularly with respect to magnetic field homogeneity (shimming), water suppression, and infiltration of subcutaneous fat signal into voxels other than just those adjacent to the scalp. Cendes et al.⁴⁶ noted that anterior temporal lobe structures were more accessible to single voxel methods, and reported only posterior and midtemporal results from their CSI study and Xue et al.⁴⁸ have reported problems with suboptimal shimming when performing CSI in a large

Figure 5 Functional MR image showing the area of increased signal associated with leg movement near a tumor thought to involve the motor strip: (a) baseline image; (b) activation image; (c) superimposition image

Figure 6 (a) Signal change associated with the onset of a focal motor seizure in the same region in a 4 year old boy with intractable epilepsy. This activation was seen 20 s before the onset of the seizure. (b) The upper two rows (A–D and E–H) show activation seen using fMRI during two clinical seizures. After activity is first seen, images 20, 60 and 100 s later are shown (all rows). In the first row a clinical motor seizure began at the time of the third image. The lower row is a period of activation not associated with a seizure. The surface EEG suggested seizure onset in this region, and ictal single photon emission computed tomography (SPECT) localized it to this same region. The base anatomy image is the same for all these figures

region including both temporal lobes. They have therefore adopted the strategy of acquiring CSI volumes from each temporal lobe separately.

8 FUNCTIONAL MRI (fMRI)

The clinical potential of fMRI is enormous and will be dealt with in many other sections of this Encyclopedia. For clinical epilepsy the following are major applications.

8.1 Mapping of Eloquent Areas of Cortex

Epilepsy surgery entails resection of abnormal areas of cortex in order to relieve the epilepsy condition. In many cases it is important to determine the location of important functions which must not be affected by this surgery such as movement, speech, and memory. The ability of fMRI to demonstrate this eloquent cortex helps in the preoperative assessment of these patients. At present this is largely limited to the motor strip⁴⁹ (Figure 5), but demonstration of speech areas will also be important.

At the moment, many groups have produced images of signal changes during 'speech activation'. While some of these are compelling, the problem of speech activation and localization is complex, and a great deal of validation and careful interpretation of these signal changes will be required before they assume their potential importance in clinical practice.

8.2 Functional Imaging of Seizures

Functional MRI can detect cortical activation which occurs during partial motor seizures.⁵⁰ Activation can be seen in the region which is activated during seizures even when no clinical seizure occurs. Also, quite remarkably, activation could first be seen up to 1 min before the onset of clinical or EEG changes during similar seizures [Figure 6(a) and (b)]. The implication of these observations is that the vascular and oxygenation changes may precede, or at least be detectable earlier than, the EEG or clinical events which are associated with seizures. It also provides compelling evidence that subclinical activation can be identified using fMRI, and this may enable precise localization of the seizure focus in some cases. These observations allow structural and dynamic functional information to be obtained in a single, integrated, totally noninvasive, MR examination, and point the way to the future role of MR as a means of imaging neurophysiology.

9 CONCLUSION

The impact of MR and its application to clinical epilepsy is akin to the impact of the EEG in the 1940s. It is enabling abnormalities of the brain to be demonstrated by noninvasive techniques in many of these patients with epilepsy. The impact has been great in the field of epilepsy surgery where, already, patients who had previously required invasive depth electrodes, are now able to go to resective surgery directly based on noninvasive studies which include noninvasive EEG, routine clinical evaluation, and these new MR techniques. In the broader field of clinical epilepsy problems, MR findings are beginning to have a large impact on the view of epilepsy, and of the syndromes that can be defined in individual patients. This will ultimately affect the classification of epilepsy, with new syndromes such as temporal lobe epilepsy with hippocampal sclerosis being defined. The consequence of these new MR techniques will be to benefit those who are most affected by this disease: patients with epilepsy.

Subsequently lecturer then senior lecturer and Honorary Consultant in Paediatric Neurology at the Institute of Child Health, and Great Ormond Street Hospital and NHS Trust, London, 1992–1996. Director of the Brain Imaging Research Institute, Austin and Repatriation Medical Centre, Heidelberg, West Australia 1996–current. Howard Florey Institute, University of Melbourne 1998–current. Current research specialities: MR applications in epilepsy, neurotoxicity.

Alan Connelly. *b* 1955. B.Sc. (Hons) Chemistry, University of Glasgow, Scotland, 1977; Ph.D., University of East Anglia, Norwich, UK. Ph.D. in high resolution NMR under the supervision of Prof. Robin Harris. Began work on in vivo spectroscopy and imaging as NMR development scientist at Oxford Research Systems, UK, 1983–88. Subsequently lecturer (1988–93) then senior lecturer (1993–present) at the Institute of Child Health, London, UK. Current research specialities: imaging and spectroscopy applications in stroke and epilepsy.

Systemically Induced Encephalopathies: Newer Clinical Applications of MRS

Brian D. Ross, Stefan Bluml, Kay J. Seymour,
Jeannie Tan, Jong-Hee Hwang and Alexander Lin

Huntington Medical Research Institutes, Pasadena, CA, USA

1 SYSTEMICALLY INDUCED ENCEPHALOPATHIES

1.1 Background: Biochemistry of Coma

Metabolic disturbances of liver, kidney, endocrine or other systems have remote effects; those on the brain result in a variety of well-defined encephalopathies. When severe, these disorders present as coma. Posner and Plum published a comprehensive account of human coma.^{1,2} Many were the result of presumed metabolic events with normal brain anatomy, setting the stage for noninvasive elucidation by means of biochemically based techniques. Among these are MRA, diffusion imaging, positron emission tomography (PET), single-photon emission tomography (SPECT), and multinuclear magnetic resonance spectroscopy (MRS). MRS has increasingly been used to identify specific biochemical changes in the brain, from which information on diagnosis and pathogenesis of these poorly understood disorders is beginning to emerge.

As a model for this group of disorders, we discuss hepatic encephalopathy, with additional remarks about diabetic, hyperosmolar, and hypoxia-induced encephalopathies. Renewed interest in the use of MRS for differential diagnosis of focal brain pathologies is reflected in studies of stroke and adrenoleukodystrophy.

1.2 Neurochemical Pathology of Hepatic Encephalopathy

Hepatic encephalopathy (HE) is an excellent example of metabolic encephalopathy,³ with identifiable neurotoxins originating in a systemic disease. In animal studies, several distinct neurotoxins have been identified. The earliest of these was ammonia;^{4,5} ammonia is normally fully removed from portal blood by hepatic urea synthesis.^{6,7} The combination of the loss of biosynthetic liver function and the diversion of nondetoxified blood to the brain by so-called portal systemic shunts (PSSs) accounts for the frequently demonstrated excess of cerebral and cerebrospinal fluid glutamine⁸ [Equation (1)].

The enzyme glutamine synthetase (GS) responsible for this reaction is located exclusively in astrocytes.⁹ Resynthesis of

glutamate and of γ -aminobutyrate (GABA) from glutamine (both vital neurotransmitter amino acids) occurs principally in neurons.¹⁰

Lest it be thought that ammonia 'toxicity' accounts for all of the clinical syndromes covered by the term HE, the interested reader is referred to Butterworth¹¹ for an extensive review of several other well-documented alternatives. Metabolic theories abound: failure of oxidative energy metabolism (a corollary of glutamate and 2-oxoglutarate depletion from the Krebs cycle), tryptophan and serotonin (5-hydroxytryptamine) accumulation, branched-chain amino acid deficits, endogenous benzodiazepine agonists which modify access of GABA to its inhibitory receptors, and neurotoxic fatty acids, octanoate in particular, have been proposed.

An attractive unifying theory proposed by Zieve¹² is that multiple neurotoxins derived from liver, blood, or from the diet, gain access via PSSs to a previously 'sensitized' brain. No mechanism of sensitization is known, but with the advent of MRS, a candidate has been proposed in the form of cerebral *myo*-inositol (mI) depletion.¹³

1.3 Animal Studies in Hepatic Encephalopathy Using Multinuclear MRS

Three groups^{14–16} independently perfected methods for the noninvasive determination of cerebral glutamine (including a variable contribution from glutamate in each assay) with ¹H MRS and confirmed the elevation of this metabolite in a variety of animal models of acute liver 'failure' with HE. One of these groups¹⁴ also demonstrated a hitherto unrecognized abnormality, the significant reduction of choline (Cho; cerebral choline-containing compounds) in the ¹H spectra of rats with acute HE.

More recently, ¹⁵N NMR^{17–19} and ¹H–¹⁵N heteronuclear multiple quantum coherence (HMQC)^{20,21} identified cerebral glutamine unequivocally in vivo in HE produced by ammonia infusion in the normal and portocaval shunted rat, respectively.

The glutamine protons coupled to amide nitrogen (termed H_Z and H_E) provide additional information regarding the compartmentalized pH adaptation during severe ammonia-induced coma in rats.²² Alkalinization of the astrocyte (glial) cell cytoplasm can be inferred from alterations in ¹H–¹⁵N HMQC spectral line-widths in vivo, whereas whole brain pH, determined from chemical shift of inorganic phosphate (³¹P MRS, *pH Measurement In Vivo in Whole Body Systems*) is apparently unaltered.²³

In extracts of portacaval shunt rat brain, high-performance liquid chromatography (HPLC) confirms the accumulation of glutamine and the depletion of glycerophosphorylcholine (GPC). The latter has also been demonstrated in human subjects using a technique of quantitative proton-decoupled ³¹P MRS.²⁴ It partly explains the reduced Cho in the prior ¹H NMR study as well as demonstrating the expected depletion by 50% or more of the cerebral mI and *scyllo*-inositol (sI) content.²⁵ This result in rats confirmed the observations that first emerged from human studies with short-echo time ¹H MRS^{13,26,27} and establishes the validity of the portacaval shunt rat for future experimental studies.

1.4 Pathogenesis, Diagnosis, and Therapeutic Management of Hepatic Encephalopathy in Humans: The Emerging Role of Proton MRS

Studies using stimulated echo acquisition mode (STEAM) localized, short echo time ^1H MRS defined the changes in 10 patients with clinically confirmed chronic HE. The average increase in cerebral glutamine was estimated as +50%, Cho decreased 14% and mI decreased by 45%²¹ (Figure 1). Very similar findings have now been reported at 2 T by Bruhn (Figure 2)^{26,29} and by McConnell³⁰ using PRESS at short or long echo times. An early study which used long echo time PRESS-localized ^1H MRS failed to identify the depletion of mI but was the first clearly to show 'Cho' depletion in human brain.³¹

Figure 1 Development of hepatic encephalopathy in human subjects (1.5 T spectra). A series of spectra of parietal cortex (white matter) acquired under closely similar conditions (GE Signa 1.5 T, STEAM localization TR 1.5 s, TE 30 ms, NEX 128) from different patients is presented. A normal spectrum for comparison is that in Figure 7(b). In liver disease (top) there is a relatively normal spectrum with a slight decrease in choline (Cho). In subclinical hepatic encephalopathy (SCHE) there is a definite decrease in *myo*-inositol (mI) with a minor increase in the glutamine (Gln) regions (glutamine plus glutamate, Glx). There is a very significant increase in the Glx regions in HE (grade 1) and mI is further depleted. The spectrum of grade 3 HE shows more severe changes in the biochemical markers of this disease, most notably glutamine. Cr, creatine

Figure 2 Identification of glutamine in the proton spectra at 2.0 T. A 51-year-old patient with HE resulting from surgical portacaval shunt (b) is compared with a normal control (a). Spectra were obtained from an occipital gray matter location and show the expected changes of HE: increased glutamine, decreased Cho/Cr and mI/Cr. With the improved resolution at 2 T, separate analysis of glutamine and glutamate is possible. Inset are spectra from model solutions (c) 5 mM glutamate + 5 mM *N*-acetylaspartate (NAA); (d) 5 mM glutamate + 5 mM NAA, indicating that in this patient the increase in glutamine occurs without obvious depletion of cerebral glutamate. Spectra were acquired on a Siemens 2.0 T clinical spectrometer, with STEAM localization; TR 3 s, TE 20 ms. Abbreviations as in Figure 1. (Modified from Bruhn et al.,²⁶ with permission from J. Frahm, T. Michaelis and colleagues)

This information considerably alters our understanding of the pathogenesis of HE, emphasizing an underlying defect in cerebral osmoregulation in addition to the clear relationship to ammonia toxicity and glutamine accumulation by the cerebral astrocytes. Proton-decoupled ^{31}P MRS revealed additional osmotic and metabolic disturbances in patients with HE.²⁴ Quantitative analyses in 16 patients with liver disease, ten with and six without chronic hepatic encephalopathy, in four patients with hyponatremia, and in 20 age-matched normal subjects were reported (Figure 3). Patients with HE were distinguished from controls by significant reduction in cerebral nucleoside triphosphate (NTP = ATP) (2.45 ± 0.20 versus 2.91 ± 0.21 mmol kg^{-1} brain; $P < 0.0003$), inorganic phosphate ($P < 0.03$) and phosphocreatine ($P < 0.04$).

In addition to increased cerebral levels of glutamate plus glutamine (Glx) and decreased concentrations of mI, patients with HE showed reduction of total visible Cho (in ^1H MRS), GPC (0.67 ± 0.13 versus 0.92 ± 0.20 mmol kg^{-1} brain in controls; $P < 0.005$), and glycerophosphorylethanolamine (GPE) (0.40 ± 0.12 versus 0.68 ± 0.12 mmol kg^{-1} brain in controls; $P < 0.0003$) (in proton-decoupled ^{31}P MRS). Of the reduction of 'total Cho', 61% was accounted for by GPC, a cerebral osmolyte. Similar metabolic abnormalities were seen in hyponatremic patients.

The results are consistent with disturbances of cerebral osmoregulation and energy metabolism in patients with chronic HE.²⁴

1.5 Energetics of the Human Brain in Hepatic Encephalopathy

The predicted cerebral energy deficit (reduction in [ATP]) has previously only been convincingly shown in mice and tree

Figure 3 Osmotic and metabolic disturbances in hepatic encephalopathy (HE). Averaged proton-decoupled ^{31}P MRS from patients with (a) HE, (b) liver disease without HE, (c) elderly controls and (d) young controls. The averaged spectra calculated from all patients with HE can readily be distinguished from averaged spectra obtained from liver-diseased patients without HE and controls by reduced concentrations of phosphoethanolamine (PE), inorganic phosphate (Pi), glycerophosphorylethanolamine (GPE), glycerophosphorylcholine (GPC), and ATP. Furthermore, phosphocreatine (PCr) content (not obvious here owing to the expanded scale) was significantly decreased in HE. Phosphorylcholine (PC) remained normal

shrews.³² Phosphorus-31 MRS should be the easiest tool with which to establish any energy deficit in HE (as predicted) but Ross,³³ Tropp,³⁴ Chamuleau,³⁵ Barbiroli,³⁶ and Morgan³⁷ have obtained conflicting and hence unconvincing data with ^{31}P MRS on such effects in humans. Using quantitative ^1H MRS, however, Geissler and colleagues showed a small but significant increase in cerebral creatine concentration [Cr] following liver transplantation in humans.³⁸ Since [Cr] is the sum of phosphocreatine (PCr) and creatine, this may indicate that patients with HE have an 'energy deficit'. A 10% reduction of PCr and a 16% reduction of NTP (of which perhaps up to 80% of the ^{31}P signal arises from ATP) is reported by Bluml et al. in patients with HE²⁴ and is hypothesized to be a contributing factor in the complex pathogenesis of the disorder. Because ATP depletion occurred without a marked increase in glutamine accumulation, the depletion of TCA cycle intermediates,

hypothesized to limit energy metabolism,⁵ is deemed an unlikely explanation. Instead, the hypothesis proposed is that ATP depletion may occur in the astrocytes as part of a failure of astrocyte volume regulation, which is reflected in reduced concentrations of several cerebral osmolytes. In the astrocyte, a possible rate-limiting role of ATP as a co-factor for GS would be most relevant. The difficulty which has been confronted in demonstrating such an effect by ^{31}P MRS, where sensitivity is 10% that of ^1H MRS, becomes obvious. Since reduced cerebral oxygen consumption and blood flow are recognized abnormalities in HE, the ^{13}C NMR techniques pioneered by Shulman may be best suited to demonstrate the anticipated reduction in the overall rate of the Krebs cycle.³⁹

From these clinical studies, it appears that ^1H MRS, particularly if applied with effective water suppression to reveal mLI, is currently most efficient for the elucidation of pathogenesis of

HE, and also, as will be shown, for its early clinical diagnosis. Direct measurement of mI by ^{13}C NMR may become a valuable adjunct.^{40–42}

2 SUBCLINICAL HEPATIC ENCEPHALOPATHY

As indicated, HE is a group of diseases presumed to have identical etiology but presenting a great variety of distinct clinical pictures. Underlying all of them is believed to be the entity of ‘subclinical HE’ (SCHE), although it is by no means clear that the HE and coma of fulminant (very acute) liver failure, goes through any truly ‘subclinical’ phase.

Proton MRS accurately reflects the entity of SCHE,^{43,44} and in preliminary studies also appears to mirror the progressive and increasingly severe syndromes of overt HE defined by Parsons-Smith as grades 1–4 (Figure 1). Elevation of glutamine is rather more obvious at 2 T (Figure 3) but presents little difficulty at 1.5 T.

Figure 1 should not be taken as proof, however, that in the individual patient such orderly progression of neurochemical dysfunction occurs. Longitudinal studies have not been performed in sufficient numbers to be certain of this. Nevertheless, it is tempting to suggest, as Figure 1 appears to indicate, that in the brain exposed to liver ‘toxins’, Cho depletion (principally GPC) precedes the loss of mI and sI, with later accumulation of glutamine. If this sequence is correct, then perhaps ‘sensitization’ of the brain is the result of mI or Cho depletion, or both. In keeping with the theory of many years standing, increasing cerebral glutamine underlies the neurological syndromes of grades 1–4, severe, overt chronic HE, as well as, perhaps, that of acute, fulminant HE and coma. Figure 4 shows the similar but more severe neurochemical changes of Reye’s syndrome, giving an effective indication of what may be seen in acute HE.⁴⁵ Unfortunately, published spectra from patients with fulminant HE are limited and difficult to interpret.⁴⁶

2.1 Depletion of *myo*-Inositol and the Induction of Hepatic Encephalopathy

A human ‘experiment’ which goes some way towards verifying this sequence is the new interventional procedure known as TIPS (transjugular intrahepatic portal systemic shunt), which is used as a life-saving procedure in cirrhosis-induced hematemesis. Not surprisingly, TIPS induces clinical HE in up to 90% of survivors.^{47–49} Proton MRS performed both before and after TIPS in 10 patients showed a universal increase in mean intracerebral glutamine following the procedure. More importantly, in a small number of individuals in whom mI was normal prior to TIPS (these patients often show SCHE), a progressive reduction in mI/Cr and development of subclinical and clinical HE follows the introduction of the shunt (Figure 5).

2.2 Restoration of Cerebral *myo*-Inositol and Choline Accompanies Reversal of Hepatic Encephalopathy

Yet another common human ‘experiment’, that of orthotopic liver transplantation, allows the reverse process to be unequivocally demonstrated, thereby establishing a firm, albeit

Figure 4 Proton MRS in acute hepatic encephalopathy caused by Reye’s syndrome. In vivo proton MRS spectra acquired from a parietal white matter region in infant brain from: (a) 10-month-old normal subject; (b) patient, day 2 after admission; (c) patient, day 8 after admission; (d) difference (b) – (c) between days 2 and 8 in patient; (e) solution with 15 mM glutamine. All spectra are scaled. Spectral assignments: Lac, lactate (1.3 ppm); NAA, *N*-acetylaspartate (2.02 ppm); Gln, glutamine (2.10–2.50 ppm, and 3.65–3.90 ppm); Cr + PCr, creatine + phosphocreatine (3.03 ppm); Cho, choline-containing compounds (3.23 ppm); mI, *myo*-inositol (3.56 ppm). U, Unassigned (3.62 ppm). Notable abnormalities concern a huge accumulation of cerebral Gln, reduced Cho, and, later, reduced mI, all of which reflect liver failure. In addition there is a decrease in NAA and [Cr] and appearance of the unassigned peak. Reye’s syndrome, a toxic viral disease associated with aspirin intake, is known to produce severe neuronal damage, and may not, therefore, completely correspond to the picture of acute liver failure. An occipital gray matter region gave almost identical results. (Reproduced with permission from Ernst et al.)⁴⁵

circumstantial link between mI depletion and the syndromes of SCHE and overt HE (Figure 6). There was also a recovery in Glx and Cho also recovered. Indeed, an overshoot of cerebral Cho is consistently observed, perhaps linking the earlier Cho

Figure 5 Effect of a transjugular intrahepatic portal systemic shunt (TIPS) on the proton MR spectrum. Spectra are from a 30-year-old female, 5 days after a hematemesis caused by esophageal varices and chronic alcoholic liver disease. Spectra acquired from a parietal white matter location (GE Signa 1.5 T, volume 12.5 cm³, STEAM TR 1.5 s TE 30 ms, NEX 128) before a TIPS procedure shows no abnormalities apart from a small but significant reduction in Cho/Cr, attributable to liver disease (top). Three weeks after TIPS, changes are seen in the Glx and mI regions and a further reduction on Cho/Cr (middle). The bottom spectrum shows the progression of changes seen (13 weeks post-TIPS); Glx is markedly increased and mI is significantly reduced. Abbreviations as in Figure 1. (With permission from Shonk et al.⁴⁸)

depletion with deficient hepatic biosynthesis of some relevant precursor of GPC.

2.3 Ornithine Transcarbamylase Deficiency

A description of MRS in HE would be incomplete without consideration of a rare but informative inborn error of hepatic urea synthesis, ornithine transcarbamylase (OTC) deficiency. The single known biochemical consequence is hyperammonemia. Gadian and colleagues⁵⁰ demonstrated the inevitable elevation of cerebral glutamine in two such patients, while Ross⁵¹ showed the extraordinary parallel with HE, in depletion of cerebral mI (Figure 7).

3 CONTRIBUTION OF NMR TO ASSESSMENT OF CLINICAL HEPATIC ENCEPHALOPATHY

3.1 Pathogenesis

Both experimentally and clinically, NMR (particularly ¹H MRS) supports the classical concept of HE as a disorder of

cerebral ammonia metabolism, be it by ammonia toxicity or glutamine synthesis (as a newer variant of the theory would have it).⁵² The concept of an underlying brain 'sensitization' receives substantial new impetus deserving of further research in animal models. Either Cho (GPC) depletion, caused perhaps by failure of hepatic synthesis of a necessary precursor, or cerebral mI depletion could fulfill the role of 'sensitizer'. In neither case is there a precedent; as a result basic research is urgently required. It is likely that NMR will play a crucial role in such investigations, and the portacaval shunt rat is a convenient model. Carbon-13 NMR is the only method of unequivocally determining mI as distinct from the lower concentrations of inositol-1-phosphate (Inos-1-P) and glycine with which mI coresonates in the ¹H MR spectrum.

3.2 Osmoregulation in Human Hepatic Encephalopathy

A new concept in HE can justifiably be attributed to these endeavors with in vivo MRS. This is related to cell-volume regulation in the brain and is conveniently termed osmolyte disorder.

GPC was first identified as an osmolyte in the kidney, while mI, GPC and taurine (in rats) were proposed for that role in brain.⁵³ Haussinger et al.⁵⁴ first used the term hypo-osmolarity to link mI with HE. The importance of the concept may lie in the hitherto obscure connection between hepatic coma (in fulminant liver failure), a disease treated as an emergency because of the massive edema that occurs (dysregulation of cerebral

Figure 6 Restoration of biochemical abnormalities post-liver transplant. The patient is a 30-year-old male with acute-on-chronic hepatic encephalopathy secondary to hepatitis, and subsequently successfully treated by liver transplantation. Spectra were acquired 6 months apart from the same parietal white matter location, (15.0 cm³ STEAM TR 1.5 s, TR 30 ms, NEX 128) and scaled to the same Cr intensity for comparison. The obvious abnormalities before liver transplantation, increased α -, β -, and γ -glutamine, reduced Cho/Cr and mI/Cr (upper spectrum) were completely reversed 3 months after transplantation, and Cho/Cr exceeded normal (lower spectrum). Abbreviations as in Figure 1

Figure 7 Treated ornithine transcarbamylase (OTC) deficiency versus healthy age-matched subject. Both spectra were acquired from a similar location in parietal white matter (STEAM TR 1.5 s, TE 30 ms, NEX 128) and processed as described in the literature.⁴⁷ Single-enzyme defects in the urea cycle result in severe hyperammonemia and 'hepatic encephalopathy'. Because the patient was receiving treatment with sodium benzoate, no excess of cerebral glutamine is present. However, as anticipated by studies in the commoner condition of hepatic encephalopathy caused by portosystemic shunting, a decrease in mI was noted in the proton spectrum of a 14-year-old with OTC deficiency (a) when compared with a normal age-matched control (b). NAA, *N*-acetylaspartate; other abbreviations as in Figure 1

osmolytes perhaps?), and the more mundane and relatively slow-evolving biochemical disturbance outlined above as chronic HE and SCHE.

3.3 Proton MRS for Diagnosis

Early in these investigations, it became apparent that mI depletion and Glx accumulation occurred when clinical HE was absent. Other systemic or metabolic diseases (apart from OTC deficiency already discussed) did not result in mI depletion; consequently ^1H MRS offers an unique opportunity for early, specific diagnosis of this still perplexing condition. Paradoxically, there is at present little enthusiasm for this, most probably because prevention (with lactulose or neomycin) and treatment (by liver transplantation) of overt or severe HE is relatively straightforward (albeit rather costly in the case of orthotopic liver transplantation (OLT) at \$150 000–200 000 per patient in USA). If a ready medical means of restoring cerebral mI were to be discovered, the value of ^1H MRS in diagnosis might increase. This point is covered in a recent report in which treatment with lactulose for 7 days in overt HE significantly increased mI/Cr.^{55,56}

3.4 Unanswered Questions in Neurology of Hepatic Encephalopathy

Wilson's disease, caused by excess copper deposition, is believed to result in an encephalopathy analogous to HE. However, the ^1H MRS findings are not surprisingly rather different, lacking either mI depletion or glutamine accumulation (unpublished study from this laboratory).

Myelopathy is an unusual form of chronic HE. It presents with paraplegia. Although neurological considerations would suggest cord involvement, the ^1H MRS findings in the parietal cortex are typical of other patients with the more classical clinical presentation (see Fig. 4 in Ross et al.).⁵¹

Often noted in MRI, the basal ganglia may be 'bright' in inversion recovery (IR) images of patients with known HE. There is no consistent relationship with ^1H MRS findings, and increasingly this MRI finding is recognized as nonspecific. Nevertheless, the extrapyramidal signs, the changes on post-mortem, and these albeit inconsistent MRI findings continue to suggest that there may be as yet unrecognized underlying neurochemical changes in the basal ganglia in HE.

4 OTHER SYSTEMIC ENCEPHALOPATHIES

4.1 Diabetes Mellitus and Ketogenesis

Like HE, diabetic encephalopathy is common and obviously 'metabolic' in origin. Three principal syndromes are recognized: diabetic ketoacidosis, lactacidosis, and nonketotic hyperosmolar coma.

Elevated cerebral glucose,⁵⁷ significant excess of mI, a reversible accumulation of 'Cho', and the presence of ketone bodies have been detected in various patients with varying severity of diabetic encephalopathy.⁵⁸ The hyperosmolar state, which is discussed in more detail below, is well known in diabetes mellitus as so-called nonketotic hyperglycemia (NKH). NKH is responsible for coma and neurological symptoms more frequently even than diabetic ketoacidosis. MRS findings in a young adult with NKH-induced coma⁵⁹ are consistent with many years of experimental work in demonstrating altered cerebral osmolytes, Cho, mI and even *N*-acetylaspartate (NAA) (Figure 8).

The most surprising finding of proton MRS, which requires further study, is the identification of acetone (rather than the more widely anticipated β -hydroxybutyrate and acetoacetate) as the ketone of human diabetic ketoacidotic encephalopathy (Figure 9).⁵⁸

A therapeutic idea dating from the 1920s has reemerged in the use of a so-called 'ketogenic diet' to provide excellent control of seizures in drug-resistant patients with epilepsy. Perhaps not surprisingly, the cerebral ketone body that accumulates in these patients is also acetone, rather than acetoacetate or β -hydroxybutyrate (Figure 10).⁶⁰ In epilepsy, we suggest that this finding is more than of academic importance and may ultimately lead to more focused dietary or pharmacological treatments. At the very minimum, ^1H MRS should be considered for clinical monitoring in iatrogenic ketosis.

Long-term neurological and cerebral 'complications' of diabetes contribute to the much increased mortality. The biochemical basis of these conditions may lie in those changes

Figure 8 Proton MRS of occipital gray matter in recovering nonketotic hyperglycemia. Excess Cho/Cr, NAA/Cr, mI/Cr (↑) as well as abnormal intensities for glucose (↗), lactate and (possibly) acetone (*) are indicated. Abbreviations as in Figure 1

in Cho, NAA, mI, ketones, and glucose, now recognized by ^{13}C and ^1H MRS to be present in the acutely and chronically diabetic brain.

4.2 The Hyperosmolar State: Identification of Idiogenic Organic Osmolytes by Proton MRS

Lien et al. first used ^1H MRS to investigate a 'new' family of cerebral metabolites collectively known as organic osmolytes because of their believed role in the maintenance of cerebral osmotic equilibrium.⁶¹ Such molecules were also first thoroughly researched in the papilla of the kidney with the help of in vitro NMR.⁶²

First in sporadic cases of diabetic hyperosmolar coma⁵⁸ and in a patient after closed head injury,^{63,64} and then most convincingly in a single infant with holoprosencephaly and deficient thirst mechanisms, these concepts were confirmed as contributing to human encephalopathy by the use of ^1H MRS (Figure 11). mI was three times normal, and other resonances, also markedly affected, returned toward normal with treatment. Difference spectroscopy is particularly helpful in identifying these changes.^{65,66} The converse, or hypoosmolar state of hyponatremia has been identified by ^1H MRS in significant numbers of patients.⁶⁷

4.3 The Hypoosmolar State: Hyponatremia and Pituitary Failure

Hyponatremia is so common that its impact on the human brain spectrum needs to be included in all discussion of clinical MRS interpretations. The characteristic features are reduction of mI/Cr and Cho/Cr in the ^1H MRS examination⁶⁷ and reduced GPE and GPC in the proton-decoupled ^{31}P spectrum.²⁴ Similarities to the findings in HE have already been discussed.

Unexpected reduction of mI/Cr or Cho/Cr, in, for example, screening MRS examinations for dementia might be an indicator of hyponatremia.⁵⁹

Central pontine myelinolysis (CPM) is a rare clinical disorder believed to follow inappropriate corrections of severe hyponatremia in patients. This link led Lien and colleagues to investigate the value of in vitro MRS of the newly discovered cerebral osmolytes in rats.⁶⁸

The correction of cerebral osmolytes disturbed by hyponatremia is even more striking than the initial discovery of their depletion because of its relevance to clinical management. Slow restoration of plasma sodium is advocated and is accompanied by even slower restoration of cerebral osmolytes. In one human study, a mean interval of 10.5 weeks elapsed before cerebral osmolyte correction in three of four patients.⁶⁷ Now we have identified the MRS pattern of CPM in a patient in whom hyponatremia was not apparent, and in whom cerebral osmolytes were normal (Figure 12). An illuminating study of

Figure 9 Diabetic ketoacidosis (DKA): cerebral ^1H spectra during two DKA episodes and recovery. (a) Episode 1, acquired 3 days after admission to hospital, at a time when the patient had supposedly totally recovered and was ready to be discharged. A peak characteristic for the presence of ketone (K) bodies was noted at 2.22 ppm, obtained from an 18 cm^3 volume in the left parietal lobe. The patient relapsed into DKA 2 days later. (b) Episode 2, acquired 5 months later from an occipital gray matter location (10.3 cm^3) during a second episode of DKA. In addition to the ketone peak, peaks for glucose (G) were seen. (c) Recovery, 6 days after episode 2 (from the same occipital location), when no more ketone bodies were detected in the urine. (d) Occipital cortex of an age- and sex-matched healthy subject. Acquisition conditions: GE Signa 1.5 T, 4X software; STEAM TR 1.5 s, TE 30 ms, NEX 128. More detailed analysis of peak K indicates the resonance frequency to be that of acetone, rather than acetoacetate, the ketone body more commonly identified in blood and urine of diabetics in coma. Abbreviations as in Figure 1. (Reproduced by permission of the Radiological Society of North America from R. Kreis and B. D. Ross, *Radiology*, 1992, **184**, 123)

Figure 10 Identification of the ketone body observed in patients on the ketogenic diet. Top trace is the summed ^1H MRS of three examinations of a patient on ketogenic diet. Lower four traces show ^1H MRS of model solutions containing 5 mmol l^{-1} of acetone, β -hydroxybutyric acid and hydroxymethyl glutaric acid, and 10 mmol l^{-1} acetoacetate. Each model solution also contained 10 mmol l^{-1} creatine as a chemical shift reference at 3.02 and 3.94. Abbreviations as in Figure 1. (Reproduced with permission from Seymour et al.)⁶⁰

hyponatremia secondary to pituitary failure suggests that some cerebral osmolytes may also be markers of hormone activity. A clearer understanding of the neuroendocrine axis may emerge from systematic use of MRS (either ^1H or ^1H - ^{31}P) in these very common disorders (Figure 13).

5 HYPOXIC ENCEPHALOPATHY AND 'BRAIN ATTACK'

The prime example of a systemically induced encephalopathy is that resulting from insufficient oxygenation of blood, with resultant failure of cerebral oxygen delivery. Hypoxic encephalopathy is best understood in the context of energy failure and altered redox state through all cerebral metabolic pathways. Loss of ATP and PCr, accumulation of ADP, AMP, inorganic phosphate, and Cr are obvious consequences; H^+ accumulates, both from failure to remove CO_2 and from formation of lactate. Reduced partners of the equilibrium enzymes lactate and glutamate dehydrogenase accumulate. In practice, glutamate is probably equally rapidly converted to glutamine. Innumerable animal studies, using principally ^{31}P NMR, but also ^1H NMR, confirm these principles and docu-

ment other previously unsuspected changes, notably the loss of the neuronal marker NAA.

The very common occurrence of hypoxic encephalopathy in humans has given ample opportunity for verification of these events in the human brain. 'Recovery' from nonlethal hypoxic encephalopathy gives yet another view of the metabolic process. From ^{31}P MRS in neonates,⁶⁹ the expected changes emerged.

More recently, ^1H MRS has been used to quantify and plot the time course of changes which occur after oxygen deprivation, applying the information to defining the degree of irreversible hypoxic neuronal damage—and hence prognosis. 'Near-drowning' is the term applied when virtually total oxygen deprivation occurs owing to submersion in water. It must be presumed that all ATP and PCr is lost, and all glucose converts to lactate in this period of anoxia. Yet at the first clinical examinations, 24 hours after rescue and artificial life support,

Figure 11 Time course of changes in principal cerebral organic osmolytes during correction of severe dehydration. A series of spectra were obtained from the same (occipital gray matter) brain location, in a 14-month-old child, recovering from severe dehydration and hypernatremia (plasma sodium 195 mmol l^{-1} ; normal range $135\text{--}142\text{ mmol l}^{-1}$) using identical acquisition conditions. Spectra were processed and scaled identically to permit subtraction of sequential spectra (difference spectroscopy). The day of examination refers to interval since admission to hospital. Examinations are numbered sequentially, from the first (Exam. 1) to last (Exam. 5) on day 36. Compared with a relevant normal [spectrum (b), Figure 7], the principal abnormality appears to be a reversal of the intensities of *N*-acetylaspartate (NAA) (reduced) and mI (increased); as a result mI dominates the spectrum. These changes slowly reverse to be nearly normal on day 36. The resultant difference spectra more clearly identify the progressively falling concentrations of several metabolites, with a possible elevation in the resonance peak assigned to the neuronal marker NAA. Quantitative MRS defines the principal abnormality as a threefold increase in the concentration of the cerebral osmolyte mI. Abbreviations as in Figure 1

Figure 12 Proton MRS of the pons in central pontine myelinolysis (CPM). (a) A 29-year-old female with characteristic MRI changes that developed in the absence of hyponatremia. The spectra [9 weeks post-insult (b); 1 month later (c)] shows marked elevation in lipid, which appropriately reflects the histology of this lesion in autopsy-proven cases of CPM. (Illustration courtesy of David Dubowitz M.D.)

MRS demonstrates more often than not the absence of lactate, normal Cr (plus PCr), and NAA at nearly full concentration. Only subsequently do NAA and total Cr fall and lactate appears. The severity of the changes gives a fairly good guide to outcome.⁷⁰

The classic events of anoxia described by Lowry⁷¹ are probably reversible, but secondary damage results in progressive cell death, the consequences of which are loss of NAA (in the case of dying neurons), loss of PCr and oxidative function and reaccumulation of lactate. It is unclear why the large accumulations of glutamine occur (Figure 14). A systematic analysis of the MRS changes and their impact on outcome after global hypoxia⁷² should go some way to clarifying the MRS literature in focal ischemia of the human brain in stroke and provide much needed noninvasive guidance in treatment of hypoxic encephalopathy. This includes tissue plasminogen activator

(TPA), neuroprotectives and other innovations in human 'brain attack'.

5.1 Chemical Shift Imaging in Acute Stroke

Most clinical questions can be quickly answered using single-voxel technique discussed in the previous section, particularly since the arrival of complete automation of voxel selection, localization, shimming, water suppression, data acquisition, phasing and semiquantitative print-out of the salient metabolite ratios.⁷³ Nevertheless, chemical shift imaging (CSI), a much more efficient use of MR signal,⁷⁴ is re-emerging for clinical questions in which multivoxel information is essential. In our opinion, only stroke (in adults) and adrenoleukodystrophy (ALD) in children completely fulfill this criterion. In

Figure 13 Endocrine-responsive hyponatremia. Proton-decoupled ³¹P MRS shows almost complete depletion of GPE and GPC [(a) pretreatment] that recovered rapidly after initiation of pituitary replacement therapy [after 1(b) and 3(c) weeks of treatment]. Inset are expanded portions of the spectra. Abbreviations as in Figure 3. (Adapted from J. Tan et al., unpublished work in this laboratory)

tumor MRS, for example, single voxel⁷⁵ matches CSI with 96–97% sensitivity for diagnosis,⁷⁶ making it generally unnecessary to use the more time-consuming CSI.

The MRS changes in chronic stroke are well documented. More recent interest in reversal therapies for acute stroke has

Figure 14 Near-drowning with fatal outcome. Brain spectrum from occipital cortex of a severe near-drowning victim (3 years old), examined 48 hours post-immersion (top), and the glutamine standard (bottom). The patient died on the 5th day post-injury. The ¹H spectrum was acquired from a volume of 12 cm³ (STEAM TR 3.0 s, TE 30 ms, data processing including correction for residual water, line fitting, and quantification as described by Kreis et al.).⁶³ The spectrum of the glutamine standard (10 mmol l⁻¹) was acquired in the same way and scaled appropriately. Notable abnormalities in the patient spectrum are the very much reduced *N*-acetylaspartate (NAA) concentration and NAA/Cr ratio, excess of lactate (doublet at 1.3 ppm), and of the strongly coupled resonances of α, β, and γ glutamine protons. A 25% reduction in [Cr] was apparent on quantitative examination. Abbreviations as in Figure 1. (Thanks to R. Kreis, T. Ernst, and E. Arcinue)

emphasized the need for very early differentiation of penumbra, infarcts and transient ischemic attacks. When cerebral artery flow falls below 100 ml min⁻¹ (normal ~130 ml min⁻¹), lactate was observed in the symptomatic cerebral cortex with increasing frequency.⁷⁷ This single-voxel study was excellent in determining differences between the affected and unaffected hemisphere and in distinguishing borderzone infarcts, territory infarcts and no infarct.⁷⁷ However, obvious regional heterogeneity could not be determined. The power of a multivoxel (single-slice) ¹H MRS acquisition in distinguishing three degrees of neurochemistry after stroke is illustrated with spectra obtained for a patient who had suffered two strokes 7 days apart (Figure 15). These are seen in T₂ MRI and in diffusion-weighted images (DWI) as bright areas. While it was readily apparent which of the two infarcts occurred first, DWI could not immediately separate the acute from the subacute lesion.

Figure 15 Chemical shift image (CSI) of acute stroke. The patient suffered a series of focal infarcts in the left internal capsule, seen in diffusion-weighted images (DWI) in left of figure. Three representative spectra (CSI, STEAM TE 135 ms) illustrates a new infarct (a), normal contralateral brain region (b) and a slightly older infarct, possibly 1 week earlier (c). Note that reduced *N*-acetylaspartate (NAA) and increased choline (Cho) are present in the early and later stages of evolving stroke. However, lactate (inverted doublet at 1.33 ppm) was present only in the more recent stroke. In this case, DWI and CSI give similar information. (Reproduced with kind permission of Stephen Holmes M.D., Queens Medical Center, Honolulu, HI)

Figure 16 Diagnostic ^1H MRS of brain abscess. Computed tomographic scan (CT) was misleadingly diagnosed as malignant tumor in a young man. MRI and ^1H MRS confirms the presence of an abscess, based upon high concentrations of bacterial breakdown products within a ring-enhancing cyst. (Reproduced with kind permission of Else R. Danielsen, University of Copenhagen, Copenhagen, Denmark)

The synchronous acquisition of spectra from each shows subtle differences between them, and from normal as determined in the unaffected hemisphere. Intuitively, it is attractive to consider lactate (present as an inverted doublet at 1.3 ppm only in the more recent 'infarct') to be the much needed marker of viable tissue. This example is merely a pilot to the much larger studies now in progress in which CSI will be performed rapidly and as part of a broader MRI protocol of DWI, MRS and perfusion imaging.

5.2 Adrenoleukodystrophy

The most common of a very rare group of inherited brain disorders of white matter, the peroxisomal disease adrenoleukodystrophy, has now been studied exhaustively with single-voxel MRS. MRS is consistently more sensitive than MRI in detection of neurologic abnormality,⁷⁸ which leads to the next

question. If MRI is normal in a leukodystrophy, where is the single voxel to be sited to achieve reliable preclinical diagnosis in this disorder? Currently we use the posterior horn of the lateral ventricle as a landmark to future disease. It would be safer to apply a robust multivoxel technique.⁷⁹

6 OTHER FOCAL BRAIN DISORDERS

There is now a huge published database on which to found the clinical practice of MRS (neurospectroscopy). In papers where original data are provided (i.e. actual spectra with details of the processing applied after acquisition), this can be reliably assumed to be transferable from one instrument to another, and even across field-strength (1.0–4.02).⁵⁹ In the USA, a CPT code (76390) signals release of MRS into the day-to-day clinical environment by virtue of its efficacy in a number of common diagnoses. Limited use has been made of the discov-

Figure 17 MRI and ^1H MRS in human neurotransplantation. MRI and MRS of an individual patient with Huntington's disease showing CNS immune response to resuming immunosuppression after halting for 6 months. Significant decrease of *N*-acetylaspartate (NAA/Cr) ratio and presence of lactate strongly suggests deterioration of graft growth without immunosuppression (middle). Abbreviations as in Figure 1

Cyclosporine Maintenance

Cyclosporine Discontinued

Figure 18 Identification of abnormal or delayed myelination with proton-decoupled ^{31}P MRS. MRS of a child with an unidentified dysmyelination syndrome who appears to lack significant amounts of white matter. (a) ^1H MRS of parietal 'white matter' shows significant reduction of Cho. An unidentified peak at 1.4 ppm is possibly lipid. (b) ^{31}P MRS with low-normal phosphodiester (PDE) for age. (c) Proton-decoupled ^{31}P MRS is markedly abnormal for a 2-year-old. GPE and GPC are reduced to the neonatal MRS level. PE and PC, however, are normal for age. Abbreviations as in Figures 1 and 3

eries reviewed in Sections 1–4, perhaps because MRI is often entirely normal! By and large, radiologists have used MRS to add detail in the differential diagnosis of lesions identified first by MRI: tumor recurrence versus necrosis, primary versus sec-

ondary tumor, stroke versus venous infarction, tumor versus stroke, abscess versus tumor in the immunocompromised patient.⁸⁰

Single-voxel ^1H MRS readily distinguishes between lymphoma, toxoplasmosis, progressive multifocal leukoencephalopathy and coccidiomycosis in patients with AIDS.⁸¹ Bacterial abscesses can no longer be confused with tumor, stroke, or multiple sclerosis plaque, since ^1H MRS identifies the abscess from its unique bacterial metabolic products (E. R. Danielsen, personal communication; Figure 16).

6.1 Central Pontine Myelinolysis

A rare focal lesion known pathologically to consist of lipid-filled macrophages similarly yields an unmistakable ^1H MR spectrum of triglyceride (see Figure 12). Lipid pathologies in the brain can be reliably studied only with short echo times. One example of a useful clinical MRS examination, prognosis after non accidental trauma (shaken-baby syndrome) hinges on identification of increasing concentrations of free lipid or 'macromolecules'⁸² in ^1H MRS.^{83,84}

6.2 Neurotransplantation in Humans

Among the neurodegenerative diseases regularly examined by ^1H MRS, only Alzheimer disease appears to have a diagnostic pattern;^{85–87} Parkinson's disease and Huntington's disease do not. In particular, earlier demonstrations of lactate in brain spectra of patients with Huntington's disease, or of excess glutamate in basal ganglia of patients with Parkinson's disease, have not been confirmed.⁸⁸

A recent study of patients who had received fetal cell transplants into the diseased putamen and caudate demonstrates a new clinical role of ^1H MRS in focal 'lesions'. The maturation, viability, partial rejection and subsequent recovery of the grafts can all be tracked in repeated ^1H MRS examinations (Figure 17).

7 ADVANCES IN MULTINUCLEAR CLINICAL NEUROSPECTROSCOPY

Human brain research with ^{31}P MRS and ^{13}C MRS are dealt with elsewhere in this series (*MRI and MRS of Neuropsychiatry; Localization and Registration Issues Important for Serial MRS Studies of Focal Brain Lesions; Central Nervous System Degenerative Disease Observed by MRI; Brain Neoplasms in Humans Studied by Phosphorus-31 NMR Spectroscopy; Brain Infection and Degenerative Disease Studied by Proton MRS and Brain MRS of Human Subjects*). In the purely clinical setting, ^{31}P MRS remains disappointing. With the exception of the discovery of a new syndrome characterized by absence of PCr from the brain spectrum⁸⁹ and the characterization of brain death as spectra lacking both PCr and ATP, few diagnostic ^{31}P MR brain spectra have been identified.

However, proton-decoupling of ^{31}P spectra has brought significant clinical advantages and several diagnostic uses to this modality. In particular, proton-decoupled ^{31}P MRS now permits accurate evaluation of the state of myelination in the

Figure 19 Clinical neurospectroscopy with ^{13}C MRS. (a) A ^1H - ^{13}C spectrum acquired in Canavan disease. Metabolite peak areas were fitted and subtracted from the spectrum (b). From the fitted curves (c) the peak ratios of Glu, Gln, and *N*-acetylaspartate (NAA) relative to mI were calculated and compared with the peak ratios obtained from a model solution containing equal concentrations of NAA, Cr, mI, glutamate, and glutamine (d). Absolute concentrations in mmol per kilogram brain tissue were calculated using [mI] quantified with ^1H MRS in the occipital region of the brain as an internal reference. Abbreviations as in Figure 1

normally developing and dysmyelinating infant brain (Figure 18).⁹⁰

The identification of other membrane or myelin disorders in adults is also gaining some specificity through the application of proton-decoupled ^{31}P MRS, since GPC, GPE, phosphorylcholine (PC) and phosphoethanolamine apparently vary almost independently in different pathological settings.⁹¹ New insights into osmolyte disturbances of hepatic encephalopathy and hyponatremia were discussed above.

From being a research tool in the 1980s, natural abundance ^{13}C MRS has achieved clinical status through identification of mI, glutamate and several other useful neurometabolites in individual patients (Figure 19).⁴¹

FDA-IND approval of $[1-^{13}\text{C}]$ -glucose (FDA 56,510; Figure 20)⁹¹ infusion allows exploration in a clinical setting of the very promising techniques developed in the 1980s at Yale.⁹² This is a dynamic technique, with many parallels to functional MRI. Carbon-13 MRS has particular relevance to the diagnosis and elucidation of the encephalopathies discussed at the beginning of this article.⁹³⁻⁹⁵

8 CONCLUSIONS

Diffuse metabolic changes in brain biochemistry are the result of complex interactions of disordered biochemistry in

Figure 20 Dynamic ^{13}C MRS after $[1-^{13}\text{C}]$ -glucose infusion. Using intravenous ^{13}C glucose infusion to enrich cerebral metabolite pools several fold higher than the 1% natural abundance (illustrated in Figure 19) provides a measure of glutamate (Glu) synthesis and metabolism. (a) Difference spectrum from a fed adult acquired 50–70 min after infusion start. Incorporation of the ^{13}C label into Glu C-4 in fasted mature (b) and immature brain (c) is clearly different and has diagnostic value in the premature infant (S. Bluml, J.-H. Wang, and B. D. Ross⁹¹)

many other organs and tissues. Hepatic encephalopathies, diabetic coma, hypo- and hyperosmolar states, endocrine and hypoxic encephalopathy are examples of such conditions in which accurate application of quantitative NMR spectroscopy sheds new light. A thorough knowledge of the clinical MRS of coma will almost certainly be of crucial importance to health care in these difficult cases. Clinical uses of ^1H MRS has focused on lesions already identified by MRI, but its uses are likely to expand. Routine clinical MRI scanners can now provide excellent informative proton-decoupled ^{31}P spectroscopy and ^{13}C brain spectra; consequently these tools too are now entering clinical use.

Temporomandibular Joint MRI

Steven E. Harms

Baylor University Medical Center, Dallas, TX, USA

1 INTRODUCTION

The value of medical imaging is determined by its ability to define treatment decisions. If those decisions are separated by treatments that greatly differ in cost or morbidity, the value of the diagnostic test is high. On the other hand, if the treatment is safe and inexpensive, then it may be more cost-effective to treat without diagnosis. As the treatment of temporomandibular joint (TMJ) disease evolves, the role of MR imaging as a determinant for clinical management decisions becomes better defined. In this chapter, the MR imaging of the TMJ is reviewed with its relationship to the current concepts for clinical management of TMJ disorders.

2 ANATOMY AND PHYSIOLOGY

The TMJ is a compound joint with the three components being the temporal bone, the mandibular condyle, and the articular disk (Figure 1). There are two joint spaces: the superior joint space lying between the disk and the temporal bone and the inferior joint space lying between the disk and the mandibular condyle.^{1,2}

The articular disk is a lens-shaped structure divided into three parts: the posterior band, the anterior band, and the thin zone. In the young asymptomatic population without previous orthodontic manipulation, the posterior band normally lies between 11 o'clock and 1 o'clock relative to the superior aspect of the mandibular condyle. As opposed to what was originally thought, the disk can be quite variable in location without producing symptoms.³

The articular disk of the TMJ is held in place by the discal ligaments which extend from the medial and the lateral poles of the condyle to the medial and lateral margins of the disk. As a result of the strong attachment to the condyle by the discal ligaments, the disk and condyle move together as a unit called the disk-condyle complex. The posterior band of the disk is connected to the posterior aspect of the temporal fossa by elastic tissues called the retrodiskal attachments. Since the retrodiskal attachment is composed of two major elastic structures, this area is sometimes called the bilaminar zone. The anterior band of the disk is attached to the superior belly of the lateral pterygoid muscle.^{1,2}

There are two movements that occur with opening: translation and rotation. The first movement is rotation which is the swinging of the condyle relative to the disk. The next movement is the translation of disk-condyle complex anteriorly from the articular fossa to a position beneath the articular eminence.^{1,2}

The disk position is primarily determined by weight bearing, with the thin zone being the point of maximum load. During mastication, weight bearing is transferred to the food between the teeth and the TMJ is unloaded. Without weight bearing to hold the thin zone in position, there is a tendency for the elastic retrodiskal tissues to pull the disk posteriorly. This force is opposed by a contraction of the anterior belly of the lateral pterygoid muscle. Disk displacement is most commonly anterior due to laxity or disruption of the elastic retrodiskal tissues that hold the disk posteriorly.^{1,2}

3 TREATMENT

Currently, most treatment teams accept the goal of TMJ treatment as relief of pain and/or restoration of function. This philosophy is a departure from the early years of TMJ treatment when restoration of normal anatomical relationships was thought to be the treatment goal. This distinction is important since relief of symptoms may be achieved in the face of abnormal anatomical relationships.

Conservative TMJ therapy may consist of approaches such as: biofeedback, nonsteroidal antiinflammatory agents, muscle relaxers, bedtime sedatives, splints, and/or any combination of these approaches. Conservative therapy generally refers to the fact these treatments are generally noninvasive and reversible. In terms of cost, however, some conservative therapy may be more expensive than surgery. It is generally accepted that a trial of some form of conservative therapy should be attempted before invasive therapy is considered. Since the decision for conservative therapy approach is based upon the symptoms and clinical settings, MRI is not typically indicated in this management decision.^{4,5}

If conservative therapy fails, then surgery may be required to relieve pain and/or restore function. There are a number of possible surgical treatments that are designed to address a particular physical defect. Joint adhesions may be treated by therapies as simple as joint lavage or as complex as arthro-

Figure 1 Normal temporomandibular joint. The bone landmarks are clearly visible on the oblique sagittal SE 15/2000 image of the temporomandibular joint. The mandibular condyle, c, and eminence, e, are labeled. Normal disk architecture is demonstrated with good demonstration of the anterior band, a, posterior band, p, and the thin zone, t

scopy.⁶ Although attempts to correct disk displacement are made by TMJ arthroscopists, it is generally recognized that the major treatment effect of arthroscopy is the lysis of joint adhesions.⁷ The lysis of adhesions is often highly effective in relieving joint symptomology without any correction in disk displacement. This discovery is a significant change from the original concept of TMJ disorders which attributed TMJ pain and dysfunction to disk displacement alone. The success of adhesion lysis therapy has made the imaging diagnosis of adhesions an important part of the MR evaluation.

Internal derangements of the articular disk can be approached with a variety of conventional surgical procedures. If the disk architecture is relatively well preserved, then disk plication may be used. The plication procedure pulls the usually anteriorly displaced disk back into position over the condyle and repairs the posterior attachment. Disk plication was once the most common surgical procedure but has fallen out of favor with many surgeons due to the common complication of adhesions in the postoperative period. In addition, abnormal disk architecture is often seen in association with displacement. Repositioning of a torn or otherwise deformed disk by plication is not possible. Diskectomy is often accompanied by replacement with a dermal graft, elastic cartilage graft, or alloplastic material.⁸ The common complication of giant cell foreign body reaction to Proplast TMJ implants has greatly reduced the use of alloplastic disk replacements.^{9,10} The poor outcome experienced with alloplastic implants has increased the popularity of autologous tissues as disk replacements. Postoperative adhesions remain a problem and despite attempts the ideal replacement material for severely degenerated or deformed disks has not yet been found.

For end-stage TMJ disorders where degeneration changes in the condyle and temporal bone predominate, the surgical treatment is often total joint replacement. A variety of appliances have been designed for total TMJ replacement. All of the devices comprise some form of artificial fossa and condyle. Because metallic components are used, MRI evaluations of the TMJ in postoperative total joint patients is not possible. As with total joint replacement in other joints, the long-term durability of the appliance is a problem. As a result, surgeons tend to restrict this approach to older individuals or to patients with severe degenerative change.¹¹

Avascular necrosis of the mandibular condyle has been described by some workers as a common cause of TMJ disorders.^{12,13} These workers favor corrections of the problem by condylar decompression or replacement. This diagnosis and treatment is highly controversial. Many in the TMJ treatment field refute this theory.

4 TECHNIQUE

The TMJ examination should consist of the following components:

1. static sagittal high-resolution images in the closed mouth position;
2. static coronal views in the closed mouth position;
3. kinematic or real time images during opening;
4. at least one sagittal T_2 -weighted series.

A dedicated TMJ surface coil is now considered an essential feature for adequate TMJ imaging. The coil may be as simple as a single 3-inch-diameter loop.¹⁴ Both sides must be evaluated simultaneously in order to demonstrate asymmetry. About 80% of TMJ disorders are bilateral. These coils can be combined either with a special combiner box or with signals separately acquired with phased array coils and receivers.^{15,16} The phased array approach will result in a theoretical square root of 2 S/N improvement but the technology is considerably more costly.

The anatomical diagnosis of most TMJ disorders is made from the high-resolution sagittal images.^{14,17-23} A short TE proton density or T_1 -weighted pulse sequence, similar to the technique used for knee imaging, is required for optimal S/N and resolution. Because volume averaging effects are an important cause of image degradation, the slice thickness should be around 3 mm. An oblique image plane is performed using the angle of the mandibular body and condyle as determined on axial scout views as a reference. The short echo anatomical images are most important in TMJ diagnosis. As a result, traditional spin echo (SE) pulse sequences are preferred over fast SE or RARE sequences due to the blurring of short, effective TE echo images.

T_2 weighting can be achieved in both a dual echo SE sequence and a separate, long, effective TE fast SE (FSE) sequence. The FSE will result in improved image resolution but the fat signal will be more intense. The fat signal can be addressed with the addition of a fat saturation prepulse which lengthens the TR . Since the objective of T_2 weighting is the identification of fluid and not anatomical definition, there is little advantage in the use of FSE over a dual echo traditional SE.^{14,17-23}

Coronal T_1 -weighted imaging is used to localize the disk in the medial-lateral direction. A faster sequence with diminished resolution compared with the sagittal images will usually be satisfactory.^{24,25}

Kinematic or real-time motion images are needed to demonstrate TMJ physiology (Figure 2). A fast T_1 -weighted SE is usually satisfactory. Gradient echo sequences may be employed if the timing parameters are adjusted to demonstrate good disk anatomy. Often gradient echo images for cine TMJ imaging are inadequate to demonstrate this anatomy and are not the favored method for this reason. Because multiple slices are needed, there is no time saving associated with the use of gradient echo sequences. Scan time on the order of one minute per view are satisfactory. At least two slices per side should be performed in case the disk moves medially or laterally out of the view of one slice. Since the condyle is the reference for disk reduction, the slices are oriented sagittally, not oblique sagittally, as in the anatomical images. The condyle is a rigid structure that must travel in a straight line in the sagittal plane. The disk, however, will tend to move anteromedially. If oblique images are performed, the late opening images will display a disk and no condyle for reference. The determination of disk reduction will require the identification of the disk relative to the condyle. For kinematic imaging, the TMJ will need to be incrementally opened at predetermined intervals. We prefer to open in 3 mm increments until the patient can no longer proceed either due to pain or inability to open. One of several commercially available patient-controlled positioning imaging devices may be employed for establishing consistent incremen-

Figure 2 Kinematic imaging. Two images from a kinematic display are shown: the closed mouth (a) and the maximum open mouth (b) views. The closed mouth view demonstrates an anteriorly displaced disk, d, relative to the mandibular condyle, c. With opening, there is poor translation of the condyle which only translates to mid-eminence, e. The disk remains anteriorly displaced throughout opening

tation. A reliable device is needed in order to quantitate the interincisor opening at the time of disk reduction.²⁶⁻²⁹

Most commercially available instruments have this kinematic display capability. Unfortunately, some manufacturers offer this capability only at additional cost. The lack of kinematic display will greatly limit the ability to make clinically significant TMJ diagnoses.

A more sophisticated and more physiologic approach is the gating of the MR imaging acquisition. Gating similar to cardiac gating is used during repetitive opening of the TMJ. It remains to be seen if this approach provides a clinically significant improvement in examination quality.

Echo planar methods may be used in the future for real-time TMJ imaging. Some believe that this approach would be more physiologic. Imaging during mastication would be possible with echo planar imaging.

5 ELEMENTS OF A TMJ INTERPRETATION

5.1 Bone

The landmarks for TMJ anatomy are the mandibular condyle and temporal bone. These structures should themselves be

evaluated for anatomic defects. Osteophytes and beaking of the mandibular condyle are common. A steep articular eminence is associated with an increased incidence of TMJ disorders. Displacement of the condyle in the fossa may be a clue as to more subtle soft tissue defects. Hypointensity of the condylar marrow may indicate avascular necrosis.^{12,13}

End-stage TMJ disorders result in severe degenerative changes. Erosions and large osteophytes are common. The eminence and condyle may be flattened. The joint space may be almost totally obliterated. If these findings are detected, a total joint replacement may be indicated.

In patients with a history of alloplastic implants, destruction of bone should be recognized as an effect associated with giant-cell foreign-body reaction. If large erosions are seen in these patients, look for an associated soft tissue mass that is hypointense on T_2 -weighted images which is the hallmark of giant-cell reaction. Fragments of implant material that are hypointense on all sequences may be identified. Giant-cell foreign-body reactions may be very severe and on occasion can penetrate through the temporal bone into the middle cranial fossa.⁸⁻¹⁰

5.2 Disk Position and Morphology

The common method for recording disk position in the closed mouth sagittal views is the relationship to the condyle. Imagine the round mandibular condyle as a clock face and then locate the posterior band of the disk. The posterior band will usually be the thickest part of the posterior aspect of the disk. Sometimes the posterior band will be flattened or the disk may be deformed with an unidentifiable posterior band. In these cases record position as the posterior aspect of the disk rather than the posterior band. The normal posterior band position is 11 o'clock to 1 o'clock; anything else is displaced. If the disk is displaced greater than the length of the disk from the fossa, then this severe displacement should be noted. Anterior displacements are the most common. Posterior displacements are rare.³⁻⁵

The position of the disk in the medial-lateral direction is demonstrated on the coronal views. If the disk is difficult to identify on the sagittal view, look on the coronal view where a pure medial or lateral displacement may be seen. Antero-medial displacements are common. Antero-lateral displacements are less commonly seen.^{24,25}

Disk morphology should be described. Are the anterior band, posterior band, and thin zone well demonstrated? If not, the disk morphology is abnormal. The disk may be thickened or distorted. A thin posterior band is a common finding in early TMJ disease.

End-stage TMJ disease results in fragmentation and degeneration. The disk may not be identifiable. Fragments of disk-like intensity may be seen. These areas commonly represent a combination of disk fragments, fibrosis, and metaplasia of the retrodiscal tissues.

Tears or perforations are findings described in TMJ arthrography as a communication of contrast from one joint space to another. Most of these perforations actually involve the retrodiscal tissues, not the disk itself. Perforations of the disk itself are rare and are almost always associated with other, more significant, abnormalities. Temporomandibular joint perforations are difficult to diagnose with MRI. With more experience, MR

imaging has demonstrated more detail of the defects that better define appropriate treatment requirements.¹⁷

5.3 Hyperintense Signal on T_2 -Weighted Images

Fluid in either the superior or inferior joint spaces is best seen on the T_2 -weighted images. As with other joints, fluid in the TMJ is a nonspecific sign of inflammation. Fluid may also be seen around the pterygoid muscle as a sign of possible myofascial disease.

Edema in the retrodiskal area indicates possible retrodiskitis. Retrodiskitis is acutely painful and often difficult to separate from an internal derangement on physical examination. The MR diagnosis of retrodiskitis is important since this disorder may be effectively treated with antiinflammatory agents. Hyperintensity in retrodiskitis begins at the posterior margin of the disk and extends posteriorly in the fossa. Often the condyle is displaced antero-inferior by the soft tissue mass. This appearance should be distinguished from normal retrodiskal veins that are hyperintense on T_2 -weighted images. These veins can be distinguished by their location, posterior and inferior compared with retrodiskitis. In contrast to retrodiskitis which is confluent, retrodiskal veins are seen as multiple, small spots typical of vessels in cross-section.¹⁷

5.4 Kinematic Evaluation

Kinematic imaging is needed to describe accurately abnormalities in joint function. Disk rotation and disk-condyle complex translation should be observed. The right and left sides should be compared side-by-side using a kinematic display.²⁶⁻²⁹

What is the relationship of the disk to the condyle during the opening cycle? If the disk is displaced in the closed mouth view, does it reduce upon opening? When does it reduce? Early or late? By knowing the interincisor distance associated with each step, the extent of opening at the point of disk reduction can be determined.

Kinematic imaging is used for the diagnosis of joint adhesions. Adhesions between the disk and the condyle are demonstrated by fixation of the disk to the condyle during the entire opening cycle. Adhesions to the eminence are shown as lack of separation between the disk and eminence as well as fixation to the eminence during opening. Asymmetric translation is indirect evidence of adhesions.

Very poor translation on physical examination is often called a closed locked joint. The classic description of closed locked physiology is an anteriorly displaced disk without reduction. Theoretically the displaced disk impairs condylar translation and locks the joint in the closed mouth position. MR studies, however, reveal that an anteriorly displaced disk, without reduction on opening, uncommonly produces locking. Other causes for a closed locked joint on physical examination should be considered. Severe adhesions can more commonly cause the clinical picture of a locked joint. When these adhesions totally encompass the condyle and prevent any translation, the condition is called fibrous ankylosis. Previous surgery with dislocated or adhered implant is another common cause of poor translation in the postoperative patient. As mentioned previously, adhesions can be managed with arthroscopy,

whereas a closed locked joint, due to disk displacement, usually requires surgery (an open surgical procedure).²⁶⁻²⁹

6 SUMMARY

There is a multifaceted spectrum of causes for TMJ-associated pain and dysfunction. As the understanding of TMJ disorders increases, the methods for treatment become more focused and more effective. Accurate diagnosis of these entities is essential in designing treatment protocol that is appropriate for a particular patient. Modern MRI methods can make the most of the diagnostic determinations needed for these treatment decisions.

1 INTRODUCTION

The first reported ^{19}F MRS experiments that applied directly to chemotherapy date from 1984, in which the metabolism of an anticancer fluoropyrimidine, 5-fluorouracil (5FU), was studied in mouse liver and a subcutaneous mouse tumor.¹ Subsequently, most preclinical ^{19}F MRS studies have indeed been concerned with 5FU and its metabolism in liver, and a variety of tumors in different animal models. This work, and other applications of ^{19}F MRS, have been extensively reviewed since the late 1980s.^{2–5} The most recent review⁶ demonstrates that ^{19}F MRS is of increasing use in the clinic and could, in the future, be used to individualize and optimize chemotherapy.

This review will briefly describe the rationale for the development of fluoropyrimidines as anticancer drugs, the key ^{19}F MRS experiments that have led to the exciting developments in the clinic, and the future mechanistic research required to realize fully the potential of this technique. Reference will also be made to other types of fluorinated compound which have been studied by ^{19}F MRS to investigate tumor hypoxia, blood flow and pH, and drug pharmacokinetics in animal models. These other studies show how ^{19}F MRS can be used at an earlier stage in drug development as a research tool.

2 5-FLUOROPYRIMIDINES: ANIMAL MODELS AND CLINICAL APPLICATIONS

The 5-fluoropyrimidine (FP) 5FU was synthesized in 1957, and is an example of rational synthesis in which the substitution of a fluorine atom for hydrogen in position 5 of the pyrimidine uracil was intended to lead to misincorporation of the drug into RNA, and inhibition of DNA synthesis.⁷ Anticancer activity is now known to be mediated via conversion to cytotoxic 5-fluoronucleotides (Fnuct) (see Figure 1). Specifically, FdUMP inhibits the key DNA synthesis enzyme thymidylate synthase (TS), FdUTP becomes misincorporated into DNA, and misincorporation of FUTP interferes with RNA maturation.⁸ Effective prodrugs of 5FU have also been synthesized which first require conversion to 5FU in the liver, or tumor, and can have a better therapeutic ratio. These prodrugs

include capecitabine and the FPs, Flox (5-fluorouridine), Tegafur (tetrahydro-2-furanyl-5-fluorouracil), and Doxfluoridine (5-deoxy-5-fluorouridine)⁹; however, 5FU remains the FP of choice, predominantly for the treatment of breast, head and neck, and gastrointestinal tumors. Despite problems with toxicity, 5FU remains the only drug with significant activity against colorectal adenocarcinoma, which is a tumor frequently metastasizing to the liver. At least 50% of 5FU is catabolized in the liver, i.e. deactivated, with probably small contributions from some types of tumors (Figure 1).^{10,11} The metabolism of 5FU can be modulated to increase cytotoxicity, e.g. by increasing Fnuct formation using methotrexate, interferon, or *N*-(phosphonacetyl)-L-aspartate (*N*-PALA), or by increasing binding of FdUMP to TS using leucovorin, or decreasing catabolism by coadministration of thymidine. Because of the relatively wide chemical shift range of ^{19}F MRS, many of the metabolites of 5FU can be resolved, especially in vitro, where pH-dependent differences in chemical shift can be exploited. It is this property, along with a relatively high sensitivity (~80% of ^1H), and the absence of a background signal, that makes ^{19}F MRS ideally suited to monitoring the pharmacokinetics of 5FU and other fluorine-containing drugs. That said, in models in vivo, and especially in the clinic, where fields of only 1.5 T are employed, the 5-fluoronucleosides (Fnucs) and Fnuct, and the fluorocatabolites (Fcat) of fluoro- β -ureidopropionic acid (FUPA) and α -fluoro- β -alanine (FBal) are not easily distinguishable. Nevertheless, 5FU, Fcat, and often Fnuct, can be detected in both liver and tumor in vivo at doses near or equivalent to those in clinical use, and this has allowed real-time pharmacokinetics to be used, which in some cases can predict tumor response. Figure 2 shows these signals, in this case those observed in a rat mammary tumor following treatment with 5FU.

DHFU, dihydrofluorouracil; FUPA, fluoro- β -ureidopropionic acid; FBal, α -fluoro- β -alanine; FUr, 5-fluorouridine; FUMP, 5-fluorouridine monophosphate; FUDP, 5-fluorouridine diphosphate; FUTP, 5-fluorouridine triphosphate; FdUr, 5-fluorodeoxyuridine; FdUMP, 5-fluorodeoxyuridine monophosphate; FdUDP, 5-fluorodeoxyuridine diphosphate; FdUTP, 5-fluorodeoxyuridine triphosphate; pyrimidine phosphoribosyl transferase

Figure 2 Fluorine-19 MRS spectra of 5FU metabolism by a chemically induced primary rat mammary tumor. Spectra (20 min blocks) were acquired at 4.7 T using a one-turn surface coil on a 5 g tumor following injection of 5FU (150 mg kg^{-1} intraperitoneally)

After the demonstration that ^{19}F MRS could detect 5FU and metabolites in vivo,¹ research was initiated to relate the amount of signal to tumor response. Decreasing doses of 5FU administered as an intravenous bolus (120 , 50 , and 25 mg kg^{-1}) to rats bearing the Walker carcinosarcoma led to decreased 5FU signal and Fnucl formed in the tumors. Tumors showed a significant response to the 50 mg kg^{-1} dose, but not to the 25 mg kg^{-1} dose.¹² Other studies^{13,14} showed a significant correlation between shrinkage of mouse (RIF-1) tumors with the amount of Fnucl formed in the tumor. Furthermore, there was a negative correlation between Fcat in the mouse liver and Fnucl formed in the tumor, indicating liver deactivation and tumor activation of 5FU were competing processes. This latter observation was important for clinical studies, where the tumor signal-to-noise ratio (S/N) may be very low, but analysis of liver signals may still be of value for prognosis. However, in these animal studies the correlation between 5FU retention in the tumor and response to treatment was weaker or not significant.^{13–15} Detection of increased Fnucl formation by ^{19}F NMR, signifying increased cytotoxicity, has also been recorded in ascites tumor cells.¹⁶

Modulation of 5FU metabolism by a range of substances, including allopurinol,¹² methotrexate,^{17–20} interferon^{20,21}, N-PALA and leucovorin,²⁰ and thymidine,^{21,22} has been observed in animal tumor models. In some cases this has been shown to lead to a change in the half-life ($t_{1/2}$) for 5FU clearance,^{12,13,18,21,22} and, more significantly, to an increase in the rate^{18,19} and final amount of Fnucl formed;^{17–19,21,22} results that have also been confirmed in extracts.^{12,18–21} In general, the

biochemical basis for these modulations is fairly well established. Fluorine-19 MRS demonstrated this could be observed in situ, noninvasively, and in real time, providing additional data on the rate of elimination of 5FU from the tumor, which normally can only be obtained by biopsy, indirectly via blood or urine samples, or by sacrifice of many animals. Furthermore, in some cases, increased Fnucl formation was also correlated with tumor response.^{19,22}

Besides biochemical modulation of 5FU metabolism, the tumor environment can be transiently altered to favor increased drug uptake, an approach with potentially important applications in the clinic where effective drug delivery to solid tumors can be a major problem. For example, breathing of carbon gas by rodents can lead to increased tumor blood flow and oxygenation,^{23,24,25} and in RIF-1 tumors this led to increased 5FU uptake and Fnucl formation, with a corresponding increase in tumor growth inhibition.¹⁴

In the clinic, the SNR is lower, predominantly because of the lower field strengths employed: 1.5 – 2 T. This means that in contrast to the experimental tumors in animals, generally only the 5FU and Fcat signals are observed, and rarely the cytotoxic species Fnucl. However, results accumulating in the clinic have shown correlations between 5FU retention in the tumor and patient response, whether partial, or complete.^{26–29} In three independent studies,^{26–28} 5FU signals have been observed in 78 – 100% of responders, but in only 8 – 23% of nonresponders. Furthermore, there is clearly a slower clearance of 5FU from tumors ($t_{1/2}$ of 20 – 60 min) compared with blood (8 – 20 min). This phenomenon is known as ‘tumor trapping’, and its signifi-

cance is described below. Some studies on the modulation of 5FU metabolism have also begun in the clinic, and changes have been detected using methotrexate, leucovorin, and interferon.⁶ Previously undetected, or more intense and prolonged, 5FU signals were observed, and, furthermore, when using combination chemotherapy, FNuct signals were also detected. The clinical utility of this type of information would be the detection of nonresponders during the early phases of treatment, and the optimization of scheduling for others.

A number of preclinical studies have been performed to identify the mechanism(s) for the trapping of 5FU that is observed clinically. It is already clear that the tumor energy status is likely to play a major role, since a high-energy status (high NTP/Pi ratio) would enable a more effective activation of 5FU to FNuct and would be likely to reflect a well-vascularized tumor, making 5FU access to the tumor easier. In two multinuclear MRS studies,^{15,30} there were significant correlations between the pretreatment tumor Pi, PCr, or NTP, the final amount of FNuct formed, and the response of the RIF-1¹⁵ or primary rat³⁰ tumors to 5FU treatment. Consistent with these observations, treatment with hydralazine (a vasodilator that de-energizes tumors³¹) favored the conversion of FNuct to 5FU.⁶ In contrast, in both the mouse¹⁵ and rat model,³⁰ no significant correlation was observed between the pretreatment pH measured by MRS (i.e. intracellular pH, pH_i) and treatment response. However, in a rat fibrosarcoma model, a 2.5-fold increase in the 5FU $t_{1/2}$ (increased 5FU trapping) was observed when the pH_i was reduced by increased tumor glycolysis,³² suggesting tumor pH could have a role in tumor retention of 5FU. What may be of significance is the low extracellular pH (pH_e) of solid tumors,³³ which in combination with a neutral pH_i leads to a reverse, or negative, pH gradient across the tumor plasma membrane (i.e. $-\Delta\text{pH}$).³⁴ One study using isolated tumor cells showed that 5FU uptake was increased when the $-\Delta\text{pH}$ was increased;³⁵ a similar relationship was observed in vivo.²¹ An explanation of these apparently conflicting different studies is that in the rat fibrosarcoma model, the induced decrease in pH_i probably caused a larger decrease in pH_e ,³⁵ thereby increasing the $-\Delta\text{pH}$. Consequently, it may be that pH_e and/or $-\Delta\text{pH}$ measurements in vivo will correlate with 5FU trapping. These observations on tumor pH and energy status provide a clear direction for further studies that could lead to protocols with a potentially improved therapeutic index for 5FU.

For chemotherapy, it is also beneficial to study the pharmacology of a drug in other tissues besides tumor. With respect to the FPs, this normally involves liver studies to determine the rate of drug detoxification and/or liver damage.^{11,36,37} Measurement of the rate of drug disappearance in the liver, formation or destruction of 5FU, and the appearance of catabolites, with or without rescue schedules, have been performed. In principle, these studies may also relate to tumor cytotoxicity.¹³ Similar studies have been performed clinically, the first in 1987 by Wolf et al.,³⁸ and most recently to provide parameters such as the maximal velocity of metabolic conversion, using only the proportional peak areas of the signals from 5FU and its metabolites.³⁹

The relatively high doses of 5FU used ($0.6\text{--}1\text{ g m}^{-2}\text{ d}^{-1}$ over 5 days) can also lead to a number of adverse clinical reactions including myelosuppression, diarrhea, and mucositis. The cardiotoxicity of 5FU was first reported in 1975,⁴⁰ and inci-

dences of about 8% have been reported.⁴¹ Various hypotheses were proposed to explain the cardiotoxicity of this drug, including ischemia secondary to coronary artery spasms, interaction of 5FU with the coagulation system, immunoallergic phenomena, and direct toxicity of 5FU on the myocardium.⁴² The precise biochemical mechanism underlying this cardiotoxicity was unclear. It has been suggested that the major catabolite of 5FU, Fbal, might be transformed into fluoroacetate (FAC), a highly cardiotoxic and neurotoxic poison.⁴³ Fluorine-19 MRS demonstrated, using an isolated perfused rat liver model, that although Fbal is indeed metabolized into FAC, commercial solutions of 5FU also contain 'impurities'. Degradation compounds are gradually formed in the basic medium, which is indispensable to the solubilization of 5FU. Two cardiotoxic compounds were identified: fluoroacetaldehyde, and fluorosemialdehyde malonic acid, the former being metabolized into FAC, a violent cardiotoxic compound.^{44,45}

3 OTHER FLUORINATED COMPOUNDS

Apart from the FP work described that has led directly to similar clinical studies, ^{19}F MRS has been applied to other fluorinated compounds as a research tool to investigate tumor hypoxia and pH and the pharmacokinetics of drugs in development.

The useful clinical activity of 5FU as a TS inhibitor encouraged the development of other TS inhibitors, such as the antifolate CB 3717. This drug had clinical anticancer activity against breast and hepatoma, but dose-limiting nephrotoxicity. Animal studies revealed renal and hepatic toxicity that was partly due to long-term retention of the drug. A fluorinated version of the drug, CB 3988, was synthesized to determine tissue distribution and concentration by NMR. Pharmacokinetics were studied in vivo in the mouse and rat using both surface and solenoid coils for fluorine imaging and spectroscopy.⁴⁶ These studies demonstrated, noninvasively, both hepatic and renal clearance and, ultimately, localization of the drug to the abdominal cavity. The $t_{1/2}$ values determined were similar to those measured by high-performance liquid chromatography of body fluids. Recently, another fluorinated TS inhibitor, ZD9331, has been developed and is currently in phase II/III clinical trials. Attempts to study a fluorinated alkylating agent, β,β -difluorochlorambucil, were limited because of binding of the drug to proteins in blood plasma and tumors and excessive toxicity.⁴⁷ A difluorinated nucleoside analog, gemcitabine, developed in the 1980s is now showing considerable success in the clinic against a range of solid tumors. The high doses that are used (approximately 1.5 g m^{-2}) have permitted ^{19}F -imaging in rat tumors;⁴⁸ ^{19}F MRS showed increased uptake in gemcitabine-sensitive murine human xenografts compared with less sensitive xenografts.⁴⁹

The energy state of a tumor is critical in determining chemo- and radiosensitivity, and a major regulator of this is the blood flow to the tumor. A number of methods have been applied to measure directly or indirectly tumor hypoxia, or blood supply. A number of studies have been performed using ^{19}F -labeled nitromidazoles, such as fluoromisonidazole, Ro-070741,⁴⁷ and SR-4554.⁵⁰ These are bioreductive agents that in hypoxic conditions undergo nitroreduction to reactive intermediates such as hydroxylamines, which bind to

macromolecules. Selective retention was seen in tumor compared with normal tissue, and increased retention was seen in mouse tumors that were known to have a greater hypoxic fraction.^{14,47,50} Perfluorocarbons (PFCs) are fluorinated organic molecules which provide a high S/N for ^{19}F MRS studies. The ^{19}F spin-lattice relaxation rates of the PFC resonances are sensitive to the oxygen tension (PO_2), and this has been exploited to measure tumor oxygenation. The principle has been reviewed,⁴ and new methods,⁵¹ and PFC types,^{25,52} including one with 12 equivalent fluorine atoms,⁵³ are continually developed. One group has used a PFC to demonstrate potential chemotherapeutic applications.^{24,54} A PFC emulsion was injected intraperitoneally, and 3 days later ^{19}F MRS was performed prior to and immediately following administration of the radiosensitizer nicotinamide. Highly significant increases in PO_2 were recorded in the mouse RIF-1 tumor with the maximum effect at 60–70 min posttreatment.⁵⁴

Tumor pH is another important determinant of chemotherapeutic response, as described for 5FU. Although in vivo pH is generally measured by ^{31}P MRS, a number of specific fluorinated probes have been developed by Deutsch and colleagues to measure intracellular pH.^{55,56} While these studies provided useful information on cell function, there is some doubt about their applicability to studying tumors in vivo; other probes, while confirming ^{31}P measurements of pH, have suffered from poor solubility.⁵⁷ The Fnuct formed from FPs is an unequivocal intracellular pH marker,^{12,15} although the S/N is generally low, and the composite nature of the peak (many Fnucs each with a slightly different pK_a) precludes absolute pH measurements. Nevertheless, dynamic 5FU-induced increases in tumor pH_i were recorded using Fnuct in RIF-1 tumors.¹⁴ Recently, new pH probes have been described that are sufficiently soluble and sensitive to allow studies in vivo.^{58,59} One, ZK 150471, is a difluorinated extracellular probe that has been shown to give comparable measurements of tumor pH_e when compared with a ^{31}P -pH probe.⁶⁰ The other, F6POL, is a monofluorinated probe that has been shown to measure both pH_i and pH_e in perfused rat heart⁵⁹ and may permit measurements in situ of tumors.

Finally, the fluorinated 2-deoxyglucose analog 2-fluoro-2-deoxyglucose (FDG) has been used to study glucose uptake in ascites tumors.^{61,62} Contrary to dogma, FDG metabolism does not cease with phosphorylation to FDG 6-phosphate. By ^{19}F MRS, it has been shown that FDG 6-phosphate may be epimerized to the mannose 6-phosphate derivative; this undergoes further conversions by ascites cells as well as in brain, heart, and muscle to a number of FDG metabolites.⁶² Significantly, one of these metabolites, NDP-FDM, persists for 24–48 h in ascites cells at sufficiently high concentrations to permit ^{19}F imaging, allowing the possibility of using ^{19}F imaging of FDG metabolites for the detection of tumors in the body.

4 SUMMARY

The high sensitivity of fluorine, absence of a background signal, and wide chemical shift range make the fluorine atom ideal for noninvasive measurements of drug pharmacokinetics. In some cases the fluorine is already an integral part of the drug, which allows direct applications of animal models to the clinic, with the increasingly realizable potential of optimizing

drug schedules. Other fluorinated compounds can be used as probes of tumor glycolysis, pH, and hypoxia, which are important determinants of chemo- and radiosensitivity.

1 INTRODUCTION

1.1 Value of ^{31}P NMR Spectroscopy for Studies of the Human Brain

In vivo ^{31}P NMR spectroscopy in humans was first applied in studies of muscle diseases and soft tissue tumors. Subsequently, metabolic, ischemic, and neoplastic disorders of the human brain have been studied by means of this technique. In vivo ^{31}P NMR spectroscopy offers a window to study high-energy phosphate and membrane phospholipid turnover in human neurometabolism. It also permits the noninvasive measurement of the intracellular pH in the tissue.

1.2 Problems of Tumor Diagnosis

The major diagnostic problems in oncology are: (i) early tumor detection, (ii) tumor grading, and (iii) tumor staging. After diagnosis of a malignant tumorous disease and selection of an adequate therapy, monitoring is important for the optimization of the treatment and for the prediction of the response to treatment.

The value of ^{31}P NMR spectroscopy for solving these clinical problems is not yet established, although animal experiments could clearly demonstrate the high potential of this noninvasive technique for monitoring tumor biochemistry and the response of tumors to radiation therapy and chemotherapy.¹⁻⁶

1.3 Heterogeneity of Neoplastic Tissue

Tumor tissue is heterogeneous on both macroscopic and microscopic scales. Vital and hypoxic tissue as well as necrotic cell masses and hemorrhage may coexist in tumors, reflecting regional differences in oxygen supply, vascularization, and nutrition of the cells.^{1,5} Because of the poor spatial resolution,

^{31}P NMR spectroscopy can provide only an overall picture of the metabolic state of the tumor, being completely insensitive to tissue heterogeneity below the centimeter range.

This is a particular problem when high-grade gliomas are examined in vivo by ^{31}P NMR spectroscopy. Histopathological studies show heterogeneities in these tumors, but often they are also heterogeneous macroscopically as can be detected by MR imaging. ^{31}P NMR spectra will therefore comprise different signal contributions from vital, hypoxic, and necrotic tissue within the selected voxel rather than give a metabolic fingerprint of this tumor entity. The problem is less serious in the case of the relatively homogeneous meningioma and pituitary adenoma. In any case, however, MR imaging is mandatory before each NMR spectroscopic examination in order to detect gross inhomogeneities within the tumor mass.

1.4 NMR Spectroscopic Techniques

Adequate performance of the method requires the acquisition of localized NMR spectra with high signal-to-noise ratio (SNR) and high frequency resolution. A variety of localization techniques has been developed for ^{31}P NMR spectroscopy in humans. Localization means that NMR signals are obtained from a volume of interest (VOI) in the examined organ, while signal contributions of regions outside the VOI are suppressed. Single-voxel localization methods, e.g. ISIS,⁷ and STEAM,⁸ are available that employ selective rf pulses in the presence of orthogonal magnetic field gradients. A frequently used localization technique for in vivo ^{31}P NMR spectroscopy studies of the human brain is chemical shift imaging (CSI), also called spectroscopic or metabolic imaging, which employs phase-encoding gradients in two or three spatial directions to generate a 2D or 3D array of localized spectra in one measurement process.⁹⁻¹⁴ These techniques permit the selective acquisition of ^{31}P NMR signals from regions with volumes $>30\text{ cm}^3$ within the human brain.

Frequency resolution and SNR of ^{31}P NMR spectra can be improved significantly using ^{31}P - $\{^1\text{H}\}$ double resonance. By this means multiplet splittings resulting from scalar ^{31}P - ^1H spin-spin couplings are removed (proton-decoupling¹⁵) and ^{31}P NMR signal intensities are enhanced owing to dipolar relaxation of phosphorus nuclei interacting with close protons (^{31}P - $\{^1\text{H}\}$ NOE^{16,17}).

Luyten and co-workers obtained localized (ISIS with 200 cm^3 voxel) proton-decoupled ^{31}P - $\{^1\text{H}\}$ NMR spectra with resolved phosphomonoester (PME) and phosphodiester (PDE) resonance bands from the human brain.¹⁸ The 2D ^{31}P CSI combined with ^1H irradiation to induce NOE signal enhancements yields in vivo brain spectra of good quality from 8×8 voxels with $3\text{ cm} \times 3\text{ cm} \times 4\text{ cm}$ volume each in a measurement time of 19 min.¹⁹

In general, comparison of in vivo NMR spectra without quantitative analysis is of limited value. Quantification must include the fit of the signals in the time or frequency domain to obtain chemical shifts, line widths, and a measure of signal intensity. Determination of absolute metabolite concentrations in tissue from in vivo ^{31}P NMR data would be of great value. However, this is a complicated problem and, therefore, ratios of integrated peak areas are often used for data analysis.

2 ASSESSMENT OF NEOPLASTIC BRAIN DISEASE WITH THE USE OF ^{31}P NMR SPECTROSCOPY

2.1 Detection and Differentiation of Brain Tumors

Tumor diagnosis was one of the primary issues to which ^{31}P NMR spectroscopy has been directed. The central diagnostic problem is the detection, localization, and differentiation of a tumor in its *early* stage when the neoplastic tissue mass is still very small. Because of its poor spatial resolution, ^{31}P NMR can hardly contribute to the solution of this problem. To our knowledge there is no case reported which clearly demonstrates the value of ^{31}P NMR spectroscopy for early cancer detection and where this modality was indispensable for clinical decisions.

On the other hand, the potential of ^{31}P NMR spectroscopy for tumor grading¹⁹ is believed to be high, because changes of signal intensities and linewidths of the various resonances, and of the inorganic phosphate (Pi) chemical shift (a measure of intracellular pH) are observed in tumor spectra in comparison to spectra from normal brain tissue. These effects reflect metabolic differences of tumor and surrounding unaffected tissue as well as physiological conditions related to tumor oxygenation, perfusion, microcirculation, and angiogenic activity.^{1,5,20,21}

Spectral differences are also expected when human brain tumors are examined at different growth stages. Animal experiments show strong changes of ^{31}P NMR spectra during growth (Figure 1). A progressive decrease of high-energy phosphate levels is attributed to an increase of the fraction of hypoxic cells,²² while an increase of PME and P_i intensities may result from the emergence of necrotic cells.¹ The frequently observed alkaline shift of pH in tumor tissue²⁰ is explained by necrosis.⁵

For tumor characterization, the presence of an NMR-visible compound unique to a specific type of tumor cells or tumor species would be highly important. In fact, no tumor-specific resonance has been found in *in vivo* ^{31}P NMR spectra of all tumors studied so far. Neuroepithelial and mesodermal tumors and cerebral metastases, for example, show the same resonances as spectra obtained from healthy brain tissue.^{23–25}

The ^{31}P NMR spectrum of a glioblastoma, a neuroepithelial tumor, shows a reduction of PME, P_i , PDE, and PCr relative to nucleoside 5'-triphosphate (NTP) signals [Figure 2(c)]. Heiss et al. found a similar spectral pattern in their ^{31}P NMR study of glioblastomas except for a cystic glioblastoma which produced only poor spectral SNR.²³ In contrast, Arnold et al. observed enhanced PME and barely reduced PDE levels in glioblastomas^{23,26} (Figure 3(e)). Resonance intensities from high- and low-grade astrocytomas, which were also examined in this study, did not differ significantly. In pituitary adenomas, reduced PDE and exceedingly high PME signals were found (Figure 3(b)). Segebarth et al. observed elevated PME and reduced PCr intensities in the ^{31}P NMR spectrum of a prolactinoma²⁷ (Figure 4(a)) in comparison to the spectrum from the unaffected brain region of the same patient (Figure 4(b)). Hwang et al. found reduced PDE/NTP and PCr/NTP signal intensity ratios and elevated pH values in high-grade gliomas and in a meningioma.²⁸ Similar findings were reported from other studies.^{29,30} The localized *in vivo* ^{31}P NMR spectra in Figure 2 show increased PME and decreased PDE and PCr signal intensities for the meningioma (Figure

Figure 1 Metabolic changes during tumor growth reflected in *in vivo* ^{31}P NMR spectra, showing progressive decline of high-energy phosphate signals (NTP, nucleoside 5'-triphosphate, mainly ATP, adenosine 5'-triphosphate; PCr, phosphocreatine) and an increase of inorganic phosphate (P_i) signals. The concentration of phosphomonoesters (PME), which are attributed to precursors of major membrane phospholipids, is elevated. (a) Base line spectrum and subsequent spectra recorded at (b) day 3, (c) day 7, and (d) day 11. The pH value of the tumor tissue dropped from 7.1 for (a) to 6.6 for (c). Experimental tumor: subcutaneously implanted MOPC 104E myeloma (modified from Evanochko et al.²)

2(b)),²⁴ a mesodermal tumor that originates from meningeal tissue, compared with the spectrum from healthy brain tissue (Figure 2(a)).

Negendank reviewed *in vivo* NMR data of human tumors.³¹ His evaluation shows that about 80% of all examined high-grade glioma (Kernohan III–IV) showed reduced PDE and about 50% reduced PCr signal intensities. In 96% of all examined meningioma, low PDE and low PCr signals were observed. Intracellular pH values were higher in high-grade glioma and meningioma than in normal brain tissue.

Figure 2 Localized ^{31}P NMR spectra of (a) healthy human brain tissue, (b) meningioma, and (c) glioblastoma obtained with the ISIS localization technique (modified from Heindel et al.²⁴)

Benign pituitary adenomas showed reduced PDE levels in 75% and high PME and low PCr levels in all patients examined.³¹ In all cases the observed pH was comparable to the value measured in normal brain tissue. Low PDE/NTP signal intensity ratios and elevated pH values were found in ependymoma.

In vivo ^{31}P NMR spectra from neuroepithelial tumors (glioma) and mesodermal tumors (meningioma) are similar, so this technique does not allow the differentiation between these two entities. On the other hand, the pH, which was found in the normal range for low-grade and elevated in high-grade glial tumors, may help to grade gliomas. However, discrepant pH values have also been reported.^{23,25} High pH values in post-therapy stages of soft tissue sarcomas were found to be related to necrosis.^{5,32}

In a recent study, Rutter et al. employed 1D ^{31}P CSI in vivo and detected statistically significant differences in NMR parameters of brain hemispheres of patients with untreated brain tumors (astrocytomas, glioblastomas, meningiomas).³³ PME/NTP and PDE/NTP signal intensity ratios were higher in glioblastomas and astrocytomas than in healthy brain tissue. The P_i/NTP and PCr/NTP ratios of astrocytomas were higher compared with glioblastomas and normal brain.

Figure 3 Localized ^{31}P NMR spectra in vivo of (a) normal human brain tissue and different tumors of the brain: (b) pituitary adenoma, (c) meningioma, (d) grade II astrocytoma, and (e) glioblastoma. Spectra were obtained by means of the ISIS localization technique with voxel sizes of 41–220 cm³ (modified from Arnold et al.²⁶)

2.2 Therapy Monitoring of Brain Tumors by Means of ^{31}P NMR

Studies of experimental tumors in animals by means of in vivo ^{31}P NMR spectroscopy showed significant changes of levels of phosphorus-containing metabolites during the course

Figure 4 Localized ^{31}P NMR spectra in vivo of (a) a prolactinoma and (b) the unaffected brain tissue in the same patient (modified from Segebarth et al.²⁷)

of radiation therapy and chemotherapy.^{2,3} A common feature is the decrease of high-energy phosphate signals (PCr, NTP) and of pH and the increase of Pi, PME, and PDE resonances; however, the opposite effects have also been observed.^{2,3,6} A strong increase in the Pi resonance is often accompanied by a collapse of high-energy phosphate signals, as demonstrated in animal studies (Figure 5). This effect has also been observed in a clinical study monitoring the hyperthermic regional perfusion therapy of the recurrence of a malignant melanoma.³⁴

The majority of studies on therapy monitoring by means of in vivo ^{31}P NMR spectroscopy have been performed in soft tissue tumors^{32,34-41} (for reviews, see Steen²¹ and Negendank³¹). Only a few studies focused on monitoring treatment of brain tumors, among them monitoring of radiation therapy and/or chemotherapy,^{23,24,26,27,29,42} immunotherapy,⁴³ and embolization.¹⁸

One of the first reports in this field was published in 1987 by Segebarth et al.²⁷ Figure 6 shows the ^{31}P NMR spectra obtained in a patient with invasive prolactinoma before and one and five weeks after pharmacotherapy with bromocriptine [the same patient as in Figure 4(a)]. Upon therapy the patient improved clinically while no morphological changes of the tumor were found by MR imaging. After five weeks, a small decrease of the NTP level was detected, but no pH change. Elevated pH values were observed in the tumor tissue before and one and five weeks after therapy when compared with the pH of the unaffected brain tissue.

More pronounced ^{31}P spectral effects were found after two weeks of radiation therapy in a patient with an intracranial lymphoma. The enhanced PME and the reduced PCr resonances before treatment changed to the intensities of normal tissue after a radiation dose of 24.2 Gy (Figure 7). The pH of the tumor tissue did not change. The patient improved

clinically during therapy. Similar results were obtained in the examination of a patient with a grade II astrocytoma treated with radiation therapy of 60 Gy total dose after subtotal surgical removal of the tumor.

In their ^{31}P NMR follow-up study of tumor radiation therapy, Heindel et al. examined patients with meningiomas, glioblastomas, astrocytomas, and other cerebral tumors.²⁴ NMR signal intensity changes similar to those in Figure 7, in particular a PME signal reduction, were observed in the spectra of grade II astrocytoma upon radiation therapy (Figure 8).

Arnold et al. examined four patients with malignant gliomas after intraarterial (Figure 9) and three patients after intravenous 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU) therapy.^{44,45} They found statistically significant differences of pH values upon evaluation of ^{31}P NMR spectra acquired before and after chemotherapy: i.v. application of BCNU resulted in a transient acidosis and i.a. administration of the same drug in an alkalosis in the tumor tissue. These pH changes were detected before

Figure 5 Changes of in vivo ^{31}P NMR spectra of an experimental tumor (murine methylcholanthrene-induced [Meth-A] sarcoma) upon application of recombinant human tumor necrosis factor α (rHuTNF- α). The series of spectra shows a progressive decline of high-energy phosphate signals (NTP, PCr) and a strong increase in the inorganic phosphate (Pi) level (modified from Shine et al.⁶)

Figure 6 Localized ^{31}P NMR spectra of prolactinoma obtained in a patient before and one and five weeks after the beginning of bromocriptine pharmacotherapy. The spectra were rescaled to take into account differences of measured voxel sizes (modified from Segebarth et al.²⁷)

any effects were seen by imaging modalities. The authors discuss the alkalosis after i.a. administration as being a result of cell membrane damage due to the high local drug concentration in this route of application. In soft tissue sarcomas, alkalosis was found to be associated with necrosis³² which may also be true for brain tumors.

Supersensitive catheter embolization of meningiomas with poly(vinyl alcohol) particles is performed to minimize bleeding during subsequent neurosurgery. This treatment form is suitable to validate ^{31}P NMR spectroscopy for clinical application. Since the spectra reflect the strong ischemia caused by the embolization, in vivo NMR spectroscopy should help to assess response to therapy. Employing two-dimensional CSI, increased $\text{P}_i/\beta\text{-NTP}$ signal intensity ratio was detected in meningioma the day following embolization.¹⁸ A complete depletion of the NTP pool was not observed (Figure 10).

Figure 7 Localized ^{31}P NMR spectra in vivo of intracranial lymphoma obtained (a) before and (b) after radiation therapy with a dose of 24.2 Gy (modified from Segebarth et al.²⁷)

In studies of therapy monitoring of human brain tumors by means of ^{31}P NMR spectroscopy, different tumor entities have been examined and also different treatment protocols applied. The comparability of results of independent studies can be compromised when different measurement techniques are used. Besides further progress in experimental techniques and quantification, a generally applicable examination protocol must be established. Notwithstanding these current limitations, the clinical studies presented on cerebral neoplasms demonstrate the potential of ^{31}P NMR spectroscopy for monitoring tumor therapy response in patients.

3 CONCLUSIONS

At present, clinical ^{31}P NMR spectroscopy of human brain tumors can be rated as follows:

1. The method allows an assessment noninvasively of bioenergetic status, levels of intermediates of phospholipid metabolism, intracellular pH, and the extent of necrosis within macroscopic regions of proliferating tissue in the brain.
2. Limitations in spatial localization, sensitivity, and spectral resolution prevent differential diagnosis of human brain tumors by means of ^{31}P NMR spectroscopy.
3. Tumor therapy monitoring is feasible with the use of ^{31}P NMR due to the observation of cellular energy status and membrane turnover rate, and the quantitative comparison with spectral data obtained before the beginning of therapy and from unaffected tissue.

Figure 8 Follow-up study in a patient with grade II astrocytoma. Localized ^{31}P NMR spectra obtained (a) before, (b) after 22 Gy, and (c) after completion of the radiation therapy (56 Gy) show intensity changes of phosphomonoester (PME) and phosphocreatine (PCr) resonances (modified from Heindel et al.²⁴)

Figure 9 Localized ^{31}P NMR spectra of a glioblastoma in a patient (a) before and (b) after superselective intraarterial infusion of 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU) over 3 h (modified from Arnold et al.⁴⁵)

Brain Neoplasms Studied by MRI

Andrew P. Kelly and Michael N. Brant-Zawadzki

Hoag Memorial Hospital Presbyterian, Newport Beach, CA, USA

1 INTRODUCTION

Magnetic resonance imaging (MRI) has become the imaging modality of choice for the evaluation of brain neoplasms. There are two main reasons why MRI has supplanted computerized axial tomography (CT) scanning at many institutions in the USA. First and foremost is the superior sensitivity that MRI possesses in detecting alterations in brain tissue caused by neoplasms. As location of an intracranial neoplasm is a factor with important diagnostic as well as prognostic implications, the ability of MRI to image in multiple planes is the second reason. This advantage helps to determine whether a lesion is intraaxial (of parenchymal origin, such as a glioma) versus extraaxial (of dural origin, for example, such as a meningioma).

A short article on MRI of brain neoplasms leaves important areas uncovered. For more extensive discussion of the topic, the reader is referred to the excellent recent reviews on brain neoplasms in the books edited by Stark and Bradley¹ and Atlas.²⁻⁴ Also, cross references to pertinent related subjects discussed elsewhere in this volume are given at the end of this article. The initial part of this article focuses on the general features exhibited by many brain neoplasms and why MRI is sensitive to these changes. Technical considerations behind deciding appropriate imaging pulse sequences are also discussed. The second section discusses some of the most common brain neoplasms and their characteristics, as displayed by MRI.

2 GENERAL NEOPLASM FEATURES SEEN ON MRI

MRI of the brain and its pathology takes advantage of the exponential time constants, T_1 and T_2 , exhibited by normal brain tissue, and alterations in these values caused by brain neoplasms. The reader is referred to other chapters in this volume for discussions on the complex basis of signal intensity and magnetic relaxation characteristics of normal brain and brain pathology. Essentially, calculated T_1 and T_2 values of brain tumors, such as astrocytomas, are longer than normal gray and white matter, but widespread differences exist even within single histological classifications, and attempts at histologic stratification of brain neoplasms by quantitative T_1 and T_2 relaxation analysis have proven futile.⁵ The presence of edema, hemorrhage, necrosis, cyst development, and even calcification can help characterize neoplasms in the brain.

Standard MRI sequences employed by most institutions include a sagittal short TR , short TE (T_1 -weighted) localizing sequence, axial long TR , long TE (T_2 -weighted) sequences, and axial T_1 -weighted sequences, usually obtained after adminis-

tration of a paramagnetic contrast agent such as gadolinium-DTPA. Gradient recalled sequences are sometimes added to help characterize lesions in regards to foci of hemorrhage or calcification, as these sequences optimize magnetic susceptibility effects. Additional planes are included when deemed necessary for further information on tumor location and extension. Because T_2 -weighted spin echo (SE) MRI sequences have the disadvantage of long acquisition times resulting in degradation of image quality secondary to patient motion, many scans are now performed using fast spin echo (FSE) techniques. The usefulness of FSE sequences already has been demonstrated in the imaging of pathologic intracranial conditions.^{6,7} Utilizing these techniques, a routine entire brain scan can now be completed in under 15 min.

By analyzing tumor signal intensity on different pulse sequences, some insight can be gained as to the nature of the cells making up the tumor. For example, neoplasms containing a high nuclear/cytoplasm ratio, such as lymphoma and meningioma, may display this lack of water content as low signal intensity on T_2 -weighted sequences.

3 SPECIFIC TUMOR FEATURES SEEN ON MRI

3.1 Location, Mass Effect, Infiltration and Hydrocephalus

The multiplanar capability of MRI allows the determination of the location of a tumor, i.e., intra-axial versus extraaxial, and thus helps to identify the potential cell of origin. The multiplanar capability of MRI aids in defining the extent of certain tumors that can be infiltrative, such as gliomas and primary lymphomas, which can extend via white matter tracts such as the corpus callosum. By assessing ventricular size and shape as well as gray and white matter interfaces, the presence or absence of mass effect and hydrocephalus can be determined. Recently, mass effect and necrosis, as displayed by and graded on MRI, were found to be statistically significant characteristics for grading astrocytic series gliomas, as compared with biopsy findings, which sometimes can be subject to sampling error.⁸

3.2 Edema

One of the major diagnostic advantages of MRI over CT is in the detection of brain edema, which is one of the most striking features associated with tumors. Termed 'vasogenic' edema, it is probably secondary to neovascularity devoid of the usual blood-brain barrier or stretching of normal vessels secondary to mass effect.⁹ Edema, by increasing bulk water, causes prolongation of T_1 and T_2 , as most tumors do; thus, changes detected on T_2 -weighted images actually represent tumor in addition to edema. MRI is highly sensitive to these changes, but specifically defining areas representing actual tumor versus edema is difficult if using T_2 -weighted images alone.

3.3 Necrosis and Cyst Formation

In most cases, intratumoral necrosis is considered to be a sign of a more aggressive lesion, and necrosis is well demonstrated by MRI. Necrosis can be cystic or noncystic; therefore, a varied appearance can be seen on MRI. Cystic necrosis with increased bulk water content will prolong T_1 and T_2 relaxation

Figure 1 A 16-year-old female with a large juvenile pilocytic astrocytoma occupying much of the right frontal lobe. (a) Before gadolinium-DTPA T_1 -weighted sagittal image obtained on a 1.5-T GE Signa magnet shows the large cystic tumor with a mural nodule (white arrowhead). (b) Note the dense enhancement of the mural nodule after contrast administration

times, while nonnecrotic cysts can show shortened T_1 and T_2 relaxation times due to hemorrhage and accumulation of proteinaceous debris, leading to high signal intensity on T_1 -weighted images.²

Benign or malignant lesions may have cystic components. Benign lesions, such as arachnoid cysts, will exhibit the behavior of 'true' cysts, following CSF signal intensity on all pulse sequences. Other benign cysts, such as colloid cysts or craniopharyngiomas, show greater variability in cyst components which determine signal changes on MRI. Malignant lesions may contain cystic components for a number of reasons, ranging from true tumoral cysts, to hemorrhage into solid lesions with subsequent clot lysis, and other causes of necrosis. Certain tumors may present as mural nodules in the cyst wall, particularly childhood astrocytomas and juvenile pilocytic astrocytomas, the latter having a very low malignant potential (Figure 1).

3.4 Hemorrhage in Brain Neoplasms

Many primary brain neoplasms may initially be discovered secondary to symptoms related to intratumoral hemorrhage,

which, when accompanied by vasogenic edema, can cause a confusing picture on MRI. The physics behind the appearance of blood on MRI is beyond the scope of this article, but the evolution of blood breakdown products from oxyhemoglobin through paramagnetic methemoglobin to hemosiderin is followed well by MRI and affords the potential for timing the event.⁴ Certain tumors, especially metastases from melanoma, lung and renal cell carcinoma, have a propensity to bleed, as do a small percentage of gliomas. Hemorrhage itself should not be considered specific for tumor, since most cerebral bleeds have other causes.

3.5 Use of Paramagnetic Contrast Agents and Enhancement

A highly regulated and consistent internal milieu must be maintained for optimal brain and spinal cord function. Specialized capillaries, with endothelial tight junctions, provide this 'blood-brain barrier' in the normal state, aided by foot processes from nearby astrocytes. By administration of paramagnetic contrast agents such as gadolinium-DTPA, areas of breakdown in the blood-brain barrier caused by tumor can be detected. This is most helpful in determining to a close approximation the extent of neoplasm versus edema by comparing post-gadolinium T_1 -weighted images with T_2 -weighted images. By enhancing the relaxation of nearby water protons, contrast agents can decrease T_1 values in areas where a breakdown in the blood-brain barrier has occurred. The vast majority of glioblastoma multiforme tumors will enhance in a heterogeneous, thick, irregular pattern, but it is important to note that degree of enhancement does not correlate with aggressiveness of tumor.¹⁰ Metastases also enhance in almost all instances. Contrast is most useful in detecting lesions that are isointense on T_1 -weighted images, show little edema on T_2 -weighted images, but which strongly enhance. This is seen in such tumors as meningiomas and acoustic neuromas. Post-operatively, contrast agents can help detect areas of suspected tumor recurrence or residual tumor, but these changes can be nonspecific, as discussed, below.

3.6 Postoperative Changes and Radiation

MRI with gadolinium is indicated following surgery, radiation or chemotherapy to follow tumor size, but recurrent tumor is not all that enhances. Local enhancement secondary to leptomeningeal scarring may persist for years after surgery, and only a size increase on sequential studies in a region of enhancement is likely to be definitive evidence of recurrent tumor.¹⁰

Many intracranial neoplasms now undergo radiotherapy as a mainstay for treatment, and most high-grade astrocytomas are now treated by gross resection followed by high energy local radiotherapy (radiation implants or radiosurgery). Sites of radiation necrosis can enhance and show edema, simulating tumor.¹¹

3.7 Tumoral Calcification

Certain neoplasms, such as oligodendrogliomas and craniopharyngiomas, have a tendency to display areas of calcification, but identification of tumoral calcification in itself seldom causes one to favor a particular neoplasm over another.

Secondary to the low resonant proton density of calcified tissue, calcium may be missed on MRI; when seen, it is generally noted to appear hypo- or isointense on T_1 - and T_2 -weighted spin echo sequences, and with gradient echo sequences signal loss is more profound due to the sensitivity of this method to the heterogeneous magnetic susceptibility found in calcified tissue. Recent articles have described occasional calcified brain lesion as appearing bright on T_1 -weighted images due to shortening of T_1 relaxation times by a surface relaxation mechanism.¹²

4 SPECIFIC NEOPLASMS AND CHARACTERISTICS DISPLAYED ON MRI

Since location as well as histologic subtype are important features that help determine the clinical presentation and prognosis of most brain neoplasms, an attempt has been made to categorize the most common neoplasms according to site of origin, with subcategorization according to cell of origin.

4.1 Intra-axial Lesions

4.1.1 Gliomas and Tumor of Glial Cell Origin

Almost 50% of primary brain tumors are gliomas, and three major tumor types are recognized, corresponding to types of glial cell: astrocytes, oligodendrocytes and ependymal cells. Since neoplastically transformed astrocytes give rise to 75–95% of all gliomas, the discussion here will center on astrocytomas.¹¹

The classification system providing the greatest prognostic validity is a three-level system where: grade I refers to low grade benign astrocytomas, such as the juvenile pilocytic astrocytoma; grade II indicates anaplastic astrocytoma with intermediate grade of malignancy; and grade III refers to the highly malignant astrocytomas and glioblastoma multiforme.

MRI features suggesting a more benign variety include absence of necrosis, well-defined margins, minimal edema and little mass effect. The hallmark of the glioblastoma multiforme, on the other hand, is necrosis, marked edema and mass effect, with prominent enhancement (Figure 2). Wide variability exists, however, since highly malignant and infiltrative tumors may not show edema or demonstrate significant enhancement.

The reader is referred to other texts on brain neoplasms for discussions of oligodendrogliomas and ependymomas.^{1,2}

4.1.2 Nonglial-Cell Intra-axial Tumors

Once considered rare, the frequency of primary intracranial lymphoma is increasing due to its occurrence in patients with immunodeficiencies, particularly patients with the acquired immune deficiency syndrome (AIDS). Because of this and its fairly characteristic MRI appearance, lymphoma deserves mention. More than 50% of cases are multifocal, and can exist in supratentorial and infratentorial locations. Lymphomas can infiltrate and cross the corpus callosum, a property shared with gliomas. Dense hypercellularity causes this tumor to appear isointense to hypointense on T_2 -weighted images. Most lymphomas enhance densely and homogeneously after contrast is administered, and tend to show less edema than gliomas of the

Figure 2 A 69-year-old man with a high-grade astrocytoma. (a) T_2 -weighted axial image obtained on a 1.5-T Siemens Magnetom magnet demonstrates a large necrotic tumor with extensive surrounding edema in the right temporal and parietal lobes. (b) Postgadolinium T_1 -weighted image shows the ring-enhancing mass lesion, but the edema is not as evident on this sequence

same size, although wide variability in enhancement patterns and edema can exist (Figure 3).

Medulloblastoma, a common primary intracranial neoplasm in children, is one of several tumors occurring more commonly in an infratentorial location. Other tumors commonly seen in this location include cerebellar astrocytomas, juvenile pilocytic astrocytomas, hemangioblastomas, and fourth ventricular ependymomas. Because of its usually cerebellar location, multiplanar MRI is important in diagnosis. Tending to be hypercellular like lymphoma, medulloblastoma enhances diffusely and is usually isointense to hypointense on T_2 -weighted images.¹³

An important use of MRI is in diagnosis of CSF dissemination of tumor. Termed leptomeningeal spread, this is a common pathway for this malignancy to metastasize or recur. Gadolinium-enhanced views of the brain and spinal cord are used to evaluate for CSF seeding.¹¹

In searching for *intracranial metastatic spread* from extracranial primary tumors such as breast, lung, and colon carcinomas and melanoma, MRI with gadolinium is the opti-

Figure 3 A 29-year-old male with AIDS and primary intracranial lymphoma. (a) Note the low signal intensity (black arrowhead) on this T_2 -weighted axial sequence obtained on a 1.5-T GE Sigma magnet. (b) Post-gadolinium T_1 -weighted axial image shows little enhancement in this case

mal screening test.¹⁴ Metastases incite greater edema as compared with primary tumors. The presence of multiple lesions strongly favors metastatic disease over a primary tumor such as glioma, although a small percentage of gliomas are multicentric.

4.2 Extra-axial Tumors

4.2.1 Meningiomas

Comprising 10–20% of intracranial tumors, meningiomas are the most common extra-axial tumor, with an autopsy prevalence of 1–2%.³ Common sites of occurrence include the cerebral convexities, the falx, and the sphenoid wing. Meningiomas originate from the dural layer covering the brain parenchyma.

Because most meningiomas show only a slight increase in T_1 over white matter and a T_2 within normal range for brain, they may appear mildly hypointense on T_1 -weighted images and isointense to hyperintense on T_2 -weighted images. Heterogeneous signal intensity, especially on T_2 -weighted images, may be seen secondary to vascular flow voids, calcification,

Figure 4 A 60-year-old male with a meningioma originating from the falx. (a) On this coronal T_1 -weighted precontrast image, the signal intensity of the tumor is similar to the brain parenchyma (black arrowhead). The images were obtained on a 1.5-T Siemens Magnetom magnet. (b) After gadolinium administration, the borders of this densely enhancing meningioma are easily defined

and cystic foci. Usually little mass effect or significant edema is seen, though these tumors can be quite large. A hallmark is intense enhancement after contrast administration, and a tapered extension of enhancement along the tumor base, called a 'dural tail', may be present, (Figure 4).

4.2.2 Acoustic Neuroma: a Cerebellopontine Angle Tumor

Being a relatively common site of tumor occurrence, the cerebellopontine angle (CPA) is well imaged by MRI. The prototype tumor occurring in this location is the acoustic neuroma arising from the eighth cranial nerve. On precontrast images, enlargement of the seventh and eighth cranial nerve complex is seen, and intense enhancement is demonstrated with contrast. Extension into the internal auditory canal highly suggests this tumor type.

4.2.3 Pituitary Gland Tumors

MRI has become the primary modality for diagnosis of hormone-secreting pituitary microadenomas as well as other tumors that may occur in the sella or suprasellar locations,

such as craniopharyngiomas. Coronal and sagittal pre- and post-gadolinium images are usually employed. Timing of the imaging with the administration of contrast agent is important, as enhancement of a microadenoma will be delayed compared with the normal enhancement of the rest of the gland. Larger pituitary tumors, such as macroadenomas, may displace the carotid artery or invade the cavernous sinus, both features being depicted well by MRI.

4.2.4 Other Extra-axial Tumors

Tumors may originate in the bones comprising the base of the skull, chordomas and chondrosarcoma being two such examples. A difficult area to image by CT, MRI demonstrates skull base masses well and may depict infiltrative changes in the marrow-containing portions of the skull base, as can be seen with metastatic involvement of the clivus. A number of tumors may originate in the pineal gland, and multiplanar imaging is important in identifying the pineal gland as the origin. Ependymoma, a tumor which originates in the ependymal lining cells of the ventricular system, is the most common intraventricular brain neoplasm and can cause expansion of the ventricle at the site of origin.¹⁵ Extrusion through various ventricular foramina, such as the foramen of Magendie or Luschka, highly suggest this tumor type when it originates in the fourth ventricle.

5 SUMMARY

MRI has proven its usefulness in the diagnosis and follow-up of brain neoplasms. As discussed, its major limitations are in the diagnosis of tumor recurrence after surgical excision and in distinguishing tumor recurrence from radiation necrosis. Recent developments in magnetic resonance spectroscopy (MRS) and positron emission tomography (PET) offer further help in such cases. Experimental work with proton MRS, for example, has shown that increased levels of lactate, choline and lipids may be associated with certain malignancies.¹⁶ In the future, the noninvasive assessment of brain neoplasm histology will probably combine the efforts of MRI, MRS and PET as the two latter technologies are further developed.

Body Fat Metabolism: Observation by MR Imaging and Spectroscopy

E. Louise Thomas and Jimmy D. Bell

Imperial College School of Medicine, Hammersmith Hospital, London, UK

1 INTRODUCTION

The importance of lipids in both health and disease is increasingly recognized. The major causes of morbidity and mortality in the western world include cancer, coronary heart disease (CHD), diabetes mellitus, and obesity. Lipids appear to have a major role in both treatment and prevention.^{1,2} There is, therefore, a growing need for in vivo methods for studying human lipid metabolism and investigating lipid depots in the body. The development and use of nuclear magnetic resonance (NMR) techniques of imaging (MRI) and spectroscopy (MRS) for lipid studies is a major recent advance.

Since the late 1980s, interest has increased in the use of both in vivo and in vitro NMR for investigation of human and animal metabolism. Researchers are taking advantage of the nondestructive and noninvasive nature of the technique. These characteristics are particularly important for widespread, population-based studies, which often require serial examinations.

The initial applications of in vivo NMR to the study of lipids were principally concerned with development of the NMR methodology, rather than focusing on specific biochemical problems.^{3,4} However, even at this early stage, the potential of MRI and MRS when applied to lipid metabolism could be envisaged. In this chapter, we will review the recent use of these techniques both in vivo and in vitro for investigation of human lipid metabolism and body fat composition and deposition.

2 USEFUL NUCLEI FOR NMR STUDIES OF LIPIDS

MRS with ^1H , ^2H , ^{13}C , and ^{31}P nuclei has been applied to the study of lipid metabolism in animals and humans.³⁻⁹ The ^1H nucleus has the highest natural abundance in biological tissues and is the highest sensitivity in NMR compared with other useful nuclei. In the past, the application of in vivo ^1H MRS to the study of lipids was not considered to be a useful technique. Problems arising from the intrinsically small chemical shift range resulted in severe signal overlap, which had limited its use. Recently, however, ^1H NMR has been shown to be an extremely powerful noninvasive method to determine intramuscular lipid content.^{7,8}

MRS using ^{13}C in vivo has been successfully applied to studies of lipid metabolism and adipose tissue composition.^{3,4,9} Compared with studies using ^1H , ^{13}C MRS is relatively insensitive because of the low gyromagnetic ratio and low natural

abundance (1.1%) of the ^{13}C nucleus. Its relative sensitivity is further reduced by the ^1H - ^{13}C coupling, which splits the ^{13}C signal, effectively reducing intensity. These problems are partially offset by the short relaxation times of most ^{13}C resonances, the high adipose tissue content of ^{13}C -containing compounds, and the use of decoupling techniques. Moreover, the very fact that ^{13}C has 1.1% natural abundance has been exploited by using ^{13}C -enriched metabolites in turnover studies, similar to classical ^{14}C -tracer studies.

MRS with ^2H has only had limited use in in vivo metabolic studies. The deuterium nucleus is quadrupolar ($I=1$). It has both a low gyromagnetic ratio and natural abundance (0.015%), which leads to a very low sensitivity relative to proton spectroscopy (1.45×10^{-6}). These unfavorable properties are offset by its short relaxation times and high body content (12 mmol/l), allowing its detection by natural abundance in vivo MRS. Furthermore, the tissue content can be readily increased by use of deuterated water (D_2O), a fact that Brereton et al. have utilized to great effect in lipid turnover studies.⁵

Limited information can be obtained from in vivo ^{31}P MRS of lipids because ^{31}P NMR detects only phosphate-containing compounds. Consequently, ^{31}P MRS has principally been applied to lipid studies in vitro.¹⁰⁻¹² One area of research where in vivo ^{31}P MRS has been applied is to the study of membrane phospholipids. However, as the signals from the bound phospholipids tend to be very broad, the useful resonances come principally from phospholipid precursors (phosphocholine and phosphoethanolamine) or breakdown (glycerophosphocholine and glycerophosphoethanolamine) products and, therefore, will not be discussed further in this chapter.

3 MRI OF BODY FAT CONTENT AND DISTRIBUTION

The accurate determination of total body fat content and measurement of regional fat depots has become an important issue as the contribution of body fat to diseases such as non-insulin-dependent diabetes mellitus and CHD has become clearer. There are many techniques that have long been used to give estimates of total and peripheral body fat content with varying degrees of accuracy. However, until the development of techniques such as X-ray computed tomography (CT) and MRI, it was not possible to differentiate between subcutaneous and internal fat depots (Figure 1).

Internal fat depots, in particular visceral fat, may be a key factor in disease development. CT gives an accurate direct measurement of visceral fat depots, though exposure to ionizing radiation makes whole body fat measurements, especially for serial studies, impractical; consequently only single slices tend to be acquired.

Initial studies using MRI to study body fat have focused on the validation of the technique. MRI has been validated in phantoms, animals, and human cadavers and has been shown to measure both muscle and adipose tissue in vivo accurately, showing good agreement with values produced by dissection and chemical analysis.¹³⁻¹⁷ MRI has also been compared with other techniques such as underwater weighing, anthropometry, body water dilution, impedance, and dual-energy X-ray absorptiometry (DEXA).¹⁸⁻²⁴ Generally there is good degree of

Figure 1 Typical abdominal transverse MR images showing distribution of internal and subcutaneous fat in a lean (a) and an obese (b) volunteer. Images were acquired using a rapid T_1 -weighted spin echo sequence

correlation between the different methods, though agreement between methods for individuals can be quite variable.²⁴

A wide variety of methodologies have been used in the application of MRI to the study of body fat. Different parameters and methods of data collection ranging from extrapolation of single-slice or multiple-slice acquisitions over selected regions of the body to whole body fat measurements have been used. Many studies have been published with single-slice MR data from the abdomen, generally at the level of L4/L5; however, there are significant drawbacks with this approach.

For an accurate measurement of body fat content, it is important that sufficient data be collected from the whole region of interest so that subtle changes are not missed or overinterpreted. A change or lack of change reported using single-slice CT or MRI scans from a selected region of the abdomen might not reflect the effect of the intervention on the entire adipose tissue depot. Indeed, it has previously been shown that a single

CT scan obtained at the level of the umbilicus contains a substantial amount of retroperitoneal fat, which is less metabolically active than other visceral fat depots. It has been suggested that changes occurring in the entire visceral fat depot may be 'diluted out' by the presence of the less-active retroperitoneal fat in the single slice. Factors such as this can have a profound effect on the final results and their interpretation. It is, therefore, more appropriate to collect sufficient data from the entire depot to be studied. One approach is to obtain multi-slice data from the whole body, as shown in Figure 2.

The main applications of MRI to the measurement of body fat depots in human subjects have been following interventions such as diet and exercise.^{25–27} Ross et al., using whole body MRI, have shown significant reductions in total and regional body fat content in obese subjects following a combination of diet and exercise (resistance or aerobic) and diet alone.^{25,26} They found similar changes in body composition in response

Figure 2 Transverse MR images showing distribution of internal and subcutaneous fat from a whole body MRI data set from a healthy female volunteer age 21 years, basal metabolic index 27.9 kg/m^{-2} , waist to hips girth ratio 0.81, subcutaneous fat 29.6 l, and visceral fat 2.25 l. Images were acquired using a rapid T_1 -weighted spin echo sequence from the volunteer's fingertips to her toes by acquiring 10 mm thick transverse images with 30 mm gaps between the slices

to diet combined with resistance exercise and diet combined with aerobic exercise.²⁶ Furthermore, significantly more subcutaneous fat was lost from the abdomen compared with the lower body and there was a greater loss of visceral fat from the upper than from the lower abdomen. The combination of diet and exercise resulted in a greater fat loss than occurred with diet alone.²⁵ Thomas et al., also using whole body MRI, have suggested that there is a preferential loss of visceral fat in lean women following moderate aerobic exercise without dietary restriction.²⁷ Interestingly, the change in body composition was only detected using MRI; weight and body fat content measured by impedance and anthropometry were not significantly different following exercise.

A preferential loss of visceral fat has also been reported in obese individuals following dietary restriction and treatment with dexfenfluramine.^{28–31} However, these studies evaluated regional body fat distribution by measuring the area on a single MRI scan, which, as discussed above, could give misleading results.

4 IN VIVO MRS

4.1 Proton MRS

The application of in vivo proton MRS to the study of lipids has until recently been rather limited because of the small chemical shift range of ^1H resonances and the intense water signal. However, a number of researchers have shown that in vivo ^1H MRS can be used to determine noninvasively the triglyceride content within muscle cells known as intramyocellular lipids (IMCL). This is particularly important as there is evidence to suggest that these 'muscle triglycerides' may be implicated in the pathogenesis of insulin resistance. Schick et al., using ^1H MRS to detect signals from human skeletal muscle, reported that the methyl and methylene lipid signals each consisted of two well-resolved peaks (Figure 3).⁷ They suggested that the two pairs of peaks corresponded to IMCL and triacylglycerols in adipocytes between muscle fibers (extramyocellular lipids, EMCL).

Evidence in support of this interpretation has come from other groups.^{32,33} Boesch et al. compared measurement of IMCL by in vivo ^1H MRS with morphometry and chemical analysis of human biopsy samples and suggested that measurement of IMCL by ^1H MRS had the best correlation with the estimation of the 'true' level of IMCL.³² Szczepaniak et al., in a very elegant study of subjects with congenital lipodystrophy, a condition associated with almost complete absence of EMCL, showed that the in vivo ^1H NMR spectra revealed only single methylene and methyl resonances, corresponding to IMCL.³³

Using ^1H MRS, Rico-Sanz et al. have shown diversity in the level of IMCL (as well as other muscle metabolites) in human skeletal muscle.³⁴ Levels of IMCL were significantly lower in the tibialis muscle than in the soleus and gastrocnemius muscles, possibly resulting from differences in fiber type composition and deposition of metabolites owing to adaptation of the muscles for locomotion.

To date, most studies have concentrated on looking at the effects of exercise on IMCL. Boesch et al. reported a significant decrease (about 40%) in IMCL in tibialis anterior muscle

Figure 3 In vivo ^1H MR spectrum from the soleus muscle of a healthy volunteer before (a) and after (b) line fitting. Cho, choline and carnitine; TCr, creatine and phosphocreatine; $\text{ET}(-\text{CH}_2-)_n$, extracellular muscle triglycerides methylene; $\text{IT}(-\text{CH}_2-)_n$, intracellular muscle triglycerides methylene; $\text{ET}(-\text{CH}_3)_n$, extracellular muscle triglycerides methyl; $\text{IT}(-\text{CH}_3)_n$, intracellular muscle triglycerides methyl

following 3 h of intensive cycling.⁸ However, it appears that the nature and intensity of the exercise may also be important, as Rico-Sanz et al. showed no changes in IMCL levels in the tibialis, gastrocnemius, or soleus muscles following two different 90 min moderate exercise protocols.³⁵

Interestingly, there have been several reports in abstract form demonstrating that IMCL content assessed by ^1H MRS is elevated in insulin-resistant individuals.^{36,37} However, this relationship was not found in subjects from all ethnic groups.³⁷

NMR images of the leg also tend to be acquired during the spectroscopy examination. These provide additional information from which it is possible to measure subcutaneous fat, bone marrow, bone, and levels of EMCL. The role of EMCL in muscle metabolism is not fully understood, but it is thought that EMCL and IMCL may have different roles. The combination of MRI and ^1H MRS will be excellent tools for increasing our knowledge of the metabolism of these two lipid depots.

4.2 Carbon-13 MRS

High-resolution ^{13}C MRS has found widespread use in the study of lipids *in vitro*.^{38,39} In particular, the clear distinction of multiple, different fatty acid groups allows this technique to be used, often quantitatively, in studies of dietary oils.^{40–43} This degree of resolution cannot be achieved *in vivo*, which limits the utility of this technique in noninvasive human research. However, major lipid groups can be distinguished and, within these constraints, important clinical and biochemical work has been carried out using proton-coupled ^{13}C and proton-decoupled $\{^1\text{H}\}$ ^{13}C MRS. A typical ^{13}C NMR spectrum of human adipose tissue is shown in Figure 4.

Canioni et al. first showed that *in vivo* ^{13}C $\{^1\text{H}\}$ MRS could detect differences in the lipid composition of adipose tissue and liver in rats fed a diet high in polyunsaturated fatty acids.³ Further work by Sillerud et al. examined $^{13}\text{C}\{^1\text{H}\}$ NMR of triacylglycerols in rat adipocytes *in vitro* and advanced our knowledge particularly of signal assignment in biological systems.⁴⁴ Moonen et al. developed *in vivo* $^{13}\text{C}\{^1\text{H}\}$ NMR to characterize adipose tissue in human subjects.⁴ They confirmed that linoleic acid ($\text{C}_{18:2n-6}$), usually the principal polyunsaturated fatty acid present in human adipose tissue, dominated the polyunsaturated fatty acid carbon signal observed *in vivo*, allowing estimation of this stored essential fatty acid.

In vivo ^{13}C MRS has been used to study the fatty acid composition of adipose tissue in rats fed diets based on significantly different fatty acid mixtures.^{3,45,46} In animals fed fats with different fatty acid content (butter/lard, olive oil, sun-

flower oil, fish oil), clear differences were found in the *in vivo* spectra, consistent with a significant effect of dietary fatty acid intake on the tissue fatty acid profile. Progressively increasing total unsaturated and polyunsaturated fatty acid content in the diet was reflected in the adipose tissue composition. However, data from both groups appeared to show discrepancy in the results obtained by ^{13}C MRS compared with GLC, which worsened in adipose tissue from animals on a diet high in complex polyunsaturated fat, a finding later confirmed in human subjects.⁴⁷

In humans, the turnover of fatty acids in adipose tissue is slow (half-life 600 days).⁴⁸ The fatty acid profile of human subcutaneous fat, therefore, provides an index of the habitual dietary fatty acid intake over the previous 2 to 3 years.⁴⁹ This information is important for long-term epidemiological surveys but has previously been limited by the need for repeat tissue biopsies for fatty acid estimation. The application of *in vivo* ^{13}C MRS to the noninvasive analysis of adipose tissue composition is, therefore, of particular value for human nutritional studies.

Beckmann et al. have used *in vivo* ^{13}C MRS to show a significant change in human adipose tissue fatty acid composition following a fat-reduced diet, with a correlation between diet and tissue monounsaturated fatty acids.⁹ No difference was found in the degree of polyunsaturation, and this may reflect the limited period (6 months) of dietary change. Thomas et al. studied vegan subjects as a defined population, with an established long-term diet high in polyunsaturated fatty acids.⁵⁰ A significantly increased adipose tissue total unsaturated and mono- and polyunsaturated fatty acid carbon content was shown in the ^{13}C spectra from the vegan group compared with omnivore controls (Figure 5). Interestingly they found no significant differences in adipose tissue composition between vegetarian subjects and the omnivore controls.

MRS with ^{13}C has also been used to investigate the influence of maternal diet on infant adipose tissue composition. Thomas et al. compared the adipose tissue composition of breast-fed infants of women who maintained either an omnivore or a vegan diet.⁵¹ The adipose tissue composition of infants directly reflects that of their mothers, with the vegan infants having 70% more polyunsaturated fatty acid carbons than the omnivore infants. Although the consequences of essential fatty acid deficiency in formula-fed infants are well documented, less is known about the effects of very high levels of long-chain polyunsaturated fatty acids in the infant diet. The long-term effects for vegan infants having such high levels of polyunsaturated fatty acids in their diet and adipose tissue are unknown. In the same study, Thomas et al. studied the adipose tissue composition of term and pre-term infants at birth, 6 weeks, and 6 months and compared them with their mothers. They found an increase in unsaturated fatty acids with increasing gestational age and maturity (Figure 6).

The complex interactions between lipids in plasma and those in the body tissues are not fully defined and are becoming an area for NMR-based, dynamic studies of nutrition and lipid metabolism.

In vivo ^{13}C MRS has also been used in combination with GLC to study the adipose tissue composition in malnourished patients with cirrhosis of the liver.⁵² No significant differences were found in overall adipose tissue composition in the patients compared with healthy volunteers by either technique, although

Figure 4 Natural abundance *in vivo* $^{13}\text{C}\{^1\text{H}\}$ NMR spectrum of human adipose tissue, dominated by signal from triglycerides. Peak assignment (referenced to $-\text{CH}_3$): 1. $\text{C}=\text{O}$ (171.79 ppm); 2. $-\text{CH}=\text{CH}-$ (monounsaturated) and $-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}-$ (polyunsaturated) (129.83 ppm); 3. $-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}-$ (polyunsaturated) (128.13 ppm); 4. C_2 glycerol (69.21 ppm); 5. C_1 , C_3 glycerol (62.05 ppm); 6. $-\text{CH}_2\text{CH}_2-\text{CO}-\text{O}-\text{R}$ (33.93 ppm); 7. $-\text{CH}_2-\text{CH}_2-\text{CH}_3$ (32.14 ppm); 8. $-(\text{CH}_2)_n-$ (29.69 ppm); 9. $-\text{CH}_2-\text{CH}=\text{CH}-$ (27.39 ppm); 10. $-\text{CH}_2-\text{CH}_2-\text{CO}-\text{O}-\text{R}$ (25.04 ppm); 11. $-\text{CH}_2-\text{CH}_2-\text{CH}_3$ (22.94 ppm); 12. $-\text{CH}_2-\text{CH}_3$ (14.1 ppm)

Figure 5 Alkene region from natural abundance in vivo coupled ^{13}C NMR spectra of human thigh adipose tissue in vegan and omnivore subjects. Spectra are scaled to the carboxyl signal. The vegan subjects, compared with omnivores, have an increased adipose tissue content of both total unsaturated and polyunsaturated fatty acid carbons (polyunsaturated: $3.45 \pm 0.87\%$ versus $2.39 \pm 0.55\%$ of total fatty acid carbons, $p < 0.05$). This reflects at least 3 years' adherence to the vegan diet, which, in the absence of all animal products, is high in polyunsaturated fats (polyunsaturates $33.13 \pm 7.4\%$ versus $25.2 \pm 8.5\%$ total dietary fat polyunsaturated, $p < 0.05$)

GLC did reveal significant differences in individual fatty acids. Following liver transplantation and subsequent recovery, the patients were re-scanned by ^{13}C MRS. The resulting increase in body fat mass was accompanied by a preferential increase in saturated fatty acids.⁵² This may be a dietary effect, as high levels of saturated fatty acids in patients' diets following liver transplantation would result in the deposition of saturated fatty acids in the adipose tissue. Alternatively, this may be secondary to a general repletion of membrane polyunsaturated fatty

acids or the use of essential fatty acids (polyunsaturated) for biosynthesis of eicosanoids in the postoperative period.

Dimand et al. have shown that the composition of human adipose tissue may also be a useful marker of fatty acid status in diseases such as cystic fibrosis.⁵³ They found levels of polyunsaturated fatty acids to be reduced and monounsaturated fatty acids elevated in patients compared with healthy controls.

Several studies have investigated the influence of exercise on adipose tissue composition.^{27,54} Intensive exercise was shown to have a significant independent effect on adipose tissue composition, with a significant decrease in polyunsaturated fatty acids following 10 weeks of basic military training.⁵⁴ Interestingly, no changes were found in adipose tissue composition following more moderate exercise.²⁷

The use of in vivo ^{13}C MRS in humans and animals has not solely been applied to adipose tissue. Barnard et al. used in vivo $^{13}\text{C}\{^1\text{H}\}$ NMR spectroscopy to examine the hepatic fatty acid profile in rats fed fats with different fatty acid patterns.⁵⁵ The liver has a pivotal role in lipid metabolism. Hepatic receptor-mediated low-density lipoprotein (LDL) clearance is a major process controlling plasma LDL concentrations. Dietary saturated fat may increase plasma LDL by suppression of hepatic LDL-receptor activity, whereas dietary substitution with polyunsaturated fatty acids may increase hepatic LDL clearance and lower plasma LDL, possibly by increasing membrane fluidity.⁵⁶ A significant dietary effect was shown with an increasing hepatic content of unsaturated fatty acids and an increasing degree of polyunsaturation as these fatty acids increased in the diet.

Investigation of the metabolism of specific fatty acids is largely unexplored and a possible future application of ^{13}C MRS. The use of ^{13}C -labeled fatty acids to trace metabolic pathways and kinetic rates is an exciting prospect. These studies may be restricted by the limited availability of labeled fatty acids, their oxidation after administration, and the sensitivity of the system, given the pre-existing strong lipid signals. However, preliminary work has been performed by Cunnane et al. and this demonstrated the ability of in vitro $^{13}\text{C}\{^1\text{H}\}$ NMR to detect carbon-specific incorporation of injected $[\text{U}-^{13}\text{C}]$ -eicosapentaenoic acid in extracted rat liver lipids.⁵⁷

Figure 6 Fatty acid composition of adipose tissue from preterm infants and full-term infants at birth and after 6 weeks of development

4.3 Deuterium Spectroscopy

There is considerable interest in monitoring lipid turnover in both health and disease. A novel approach to the study of dynamic in vivo tissue lipid metabolism was developed by Brereton et al.⁵ They investigated the use of in vivo ^2H MRS in mice. Administration of D_2O (10% v/v) in the drinking water for 3–4 days allowed the detection of deuterium-enriched tissue lipid resonances in spectra acquired in less than 2 min, as shown in Figure 7a. The spectra consist of resonances from deuterated water (HOD) and the CHD-group of the tissue lipids. Removal of D_2O from the drinking water led to clear changes in the intensity of both signals (Figure 7b). The loss of ^2H from the water signal was significantly faster than from tissue lipids. The loss of ^2H from the lipid resonance was, therefore, proposed as a noninvasive measure of the rate of fat utilization. This method has since been applied to the study of fat utilization in obesity.

Obesity is one of the most common medical disorders and is characterized by excess adipose tissue and elevated plasma nonesterified fatty acids. Furthermore, obesity is known to lead to glucose intolerance and insulin resistance. Fat turnover, as reflected by the levels of plasma nonesterified fatty acids, may be implicated in this process. However, the lack of in vivo techniques for measuring fat utilization has greatly hampered progress in this area. Body fat turnover in mouse models of obesity and diabetes mellitus have been studied in vivo using the ^2H NMR technique.⁵⁸ Brereton et al. showed that the rates of fat utilization in obese mice were significantly lower than the rates for nonobese mice; the induction of diabetes did not affect utilization of fat as a metabolic fuel.⁵⁸ These studies clearly suggest that ^2H MRS will provide researchers with a powerful method for noninvasive assessment of fat turnover rates.

5 IN VITRO MRS

Plasma concentrations of LDL and high-density lipoproteins (HDL) are well-established markers for CHD risk assessment. Standard methods for quantification and compositional analysis of plasma lipoproteins require laborious and time-consuming physical separation based on particle size, density, or apolipoprotein content. Bell et al. have shown that MRS can be readily applied to distinguish lipoprotein fractions as well as to study alterations in plasma lipoproteins associated with dietary manipulation, both in intact plasma and in the isolated lipoprotein classes.^{11,12} For example, sophisticated computer deconvolution methods (line-fitting analysis) are being developed to identify and quantify lipoprotein fractions in the ^1H NMR spectra of intact plasma samples (500 μl) within minutes.^{59,60}

The effects of dietary manipulation on the ^1H NMR profile of lipoproteins are illustrated in Figure 8. Changes in composition following fish oil supplementation are shown by the presence of a new lipid resonance (peak 2A) arising from fish oil $n-3/\omega-3$ fatty acids incorporated into plasma lipoproteins, while the methylene $-(\text{CH}_2)_n-$ signal (peak 3) is markedly reduced. Furthermore, T_2 analysis of the lipid resonances showed that these changes in lipid composition of the LDL

Figure 7 In vivo ^2H MRS in mice. (a) Natural abundance spectrum of a mouse. The resonance linked to the CHD-group of lipids is to high field at 1 ppm. Chemical shifts were reference to the deuterated water (HOD) resonance assigned to 4.8 ppm. (b) Spectra of a mouse following the removal of 10% (v/v) D_2O from its drinking water. The spectra were recorded at 1, 4, 5, 8, 11, 15, 16 and 21 days after the resumption of normal drinking water, indicated by (a) to (h), respectively. Spectrum (i) was recorded prior to the administration of D_2O to drinking water. (Adapted with permission of Heyden & Son Ltd from I. M. Brereton, D. M. Doddrell, S. M. Oakenfull, D. Moss, and M. G. Irving, *NMR Biomed.*, 1989, 2, 55.)

particles are accompanied by alteration in the structural characteristics of these particles.¹¹

6 SUMMARY

In this chapter, we have reviewed the current state of in vivo MRS as applied to the study of lipids. It is clear that this is a relatively new area of NMR research. However, it offers

Figure 8 Expansions of spin echo ^1H NMR spectra of intact human plasma (a) before and (b) after 7 days of fish oil supplementation. Peaks 1, 2: terminal $-\text{CH}_3$ group from LDL/HDL and very-low-density lipoprotein (VLDL), respectively; peak 3: $-(\text{CH}_2)_n-$ of VLDL. Peak 2A arises from $n-3/\omega-3$ fatty acids incorporated into plasma lipoproteins

many exciting prospects for future research into human lipid metabolism and body composition.

1 INTRODUCTION

The importance of diet in both the preservation of health and treatment of disease is increasingly recognized. The major causes of morbidity and mortality in the Western world include cancer, coronary heart disease, diabetes mellitus, and obesity. Nutrition appears to have a major role both in their treatment and prevention.^{1,2} There is therefore a growing need for the application of current scientific techniques to nutritional studies, to delineate the response of human metabolism to dietary alterations. The development and use of spectroscopy for nutritional studies is a major recent advance.

The last decade has seen increasing interest in the use of both in vivo and in vitro NMR spectroscopy for investigation of human and animal metabolism. Researchers are taking advantage of the nondestructive and noninvasive nature of the technique. These characteristics are particularly important for widespread, population-based studies of human nutrition, which often require serial examinations.

The initial applications of NMR to dietary studies were principally concerned with development of the NMR methodology, rather than focusing on specific nutritional and biochemical problems.^{3,4} However, even at this early stage the potential of NMR spectroscopy when applied to lipid and glycogen metabolism could be envisaged. In this article we will review the recent use of in vivo and in vitro NMR spectroscopy for the investigation of the metabolic effects of diet.

2 USEFUL NUCLEI FOR DIETARY STUDIES

Carbon-13, ²H, ¹H and ³¹P NMR techniques have all been applied to study the effects of dietary manipulation in animals and humans.³⁻⁹ Limited information can be obtained with in vivo ³¹P and ¹H NMR spectroscopy as applied to nutrition. Phosphorus-31 NMR detects only phosphate-containing compounds; ¹H NMR suffers from a small chemical shift range, resulting in severe signal overlap and signals near the water resonance which cannot be readily detected. This has meant that ¹H and ³¹P NMR techniques have principally been applied to dietary studies in vitro.¹⁰⁻¹² However, ²H and ¹³C

NMR methods have been used in elegant in vivo metabolic studies.

The deuterium nucleus is quadrupolar ($I = 1$). It has both a low gyromagnetic ratio and natural abundance (0.015%), which leads to a very low sensitivity relative to proton spectroscopy (1.45×10^{-6}). These unfavourable properties are offset by its short relaxation times and high body content (12 mM), allowing its detection by natural abundance in vivo NMR spectroscopy. Furthermore, the tissue content can be readily increased by the use of deuterated water (D₂O), a fact that Brereton et al.⁵ have utilized to great effect in lipid turnover studies.

Carbon-13 NMR spectroscopy in vivo has also been successfully applied in dietary studies.^{3,4,8,9} Compared with ¹H NMR, ¹³C NMR spectroscopy is very insensitive due to the low gyromagnetic ratio and low natural abundance (1.1%) of the ¹³C nucleus. Its relative sensitivity is further reduced by the ¹H-¹³C coupling which splits the ¹³C signal, effectively reducing intensity. These problems are partially offset by the short relaxation times of most ¹³C resonances, the use of decoupling techniques, and the high tissue content of important dietary-related, ¹³C-containing compounds, including lipids and glycogen. Moreover, the very fact that ¹³C has 1.1% natural abundance has been exploited by using ¹³C-enriched metabolites in turnover studies, similar to classical ¹⁴C tracer studies.

3 IN VIVO NMR SPECTROSCOPY

3.1 Lipid Metabolism

3.1.1 Carbon-13 NMR Spectroscopy

High-resolution ¹³C NMR spectroscopy has found widespread use in the study of lipids in vitro.^{13,14} In particular, the clear distinction of multiple different fatty acid groups allows this technique to be used, often quantitatively, in studies of dietary oils.¹⁵⁻¹⁸ This degree of resolution cannot be achieved in vivo, which limits the utility of this technique in noninvasive human research. However, major lipid groups can be distinguished and, within these constraints, important clinical and biochemical work has been carried out using proton-coupled ¹³C and proton-decoupled ¹³C{¹H} NMR spectroscopy.

Canioni et al.³ first showed that in vivo ¹³C{¹H} NMR spectroscopy could detect differences in the lipid composition of adipose tissue and liver in rats fed a diet high in polyunsaturated fatty acids. Further work by Sillerud et al.¹⁹ examined ¹³C{¹H} NMR of triacylglycerols in rat adipocytes in vivo, advancing our knowledge particularly of signal assignment in biological systems. Moonen et al.⁴ developed in vivo ¹³C{¹H} NMR to characterize adipose tissue in human subjects. They confirmed that linoleic acid (C_{18:2n-6}), usually the principal polyunsaturated fatty acid present in human adipose tissue, dominated the polyunsaturated fatty acid carbon signal observed in vivo, allowing estimation of this stored essential fatty acid. A typical ¹³C NMR spectrum of human adipose tissue is shown in Figure 1.

Barnard et al.⁹ demonstrated the capability of in vivo ¹³C{¹H} NMR spectroscopy to monitor the effect of diet on

Figure 1 Natural abundance in vivo $^{13}\text{C}\{^1\text{H}\}$ NMR spectrum of human adipose tissue, dominated by signals from triacylglycerols. Peak assignment (referenced to $-\text{CH}_3$): 1, $\text{C}=\text{O}$ (171.79 ppm); 2, $-\text{CH}=\text{CH}-$ (monounsaturated) and $-\text{CH}=\text{CHCH}_2\text{CH}=\text{CH}-$ (polyunsaturated) (129.83 ppm); 3, $-\text{CH}=\text{CHCH}_2\text{CH}=\text{CH}-$ (polyunsaturated) (128.13 ppm); 4, C-2 glycerol (69.21 ppm); 5, C-1, C-3 glycerol (62.05 ppm); 6, $-\text{CH}_2\text{CH}_2\text{CO}_2\text{R}$ (33.93 ppm); 7, $-\text{CH}_2\text{CH}_2\text{CH}_3$ (32.14 ppm); 8, $-(\text{CH}_2)_n-$ (29.69 ppm); 9, $-\text{CH}_2\text{CH}=\text{CH}-$ (27.39 ppm); 10, $-\text{CH}_2\text{CH}_2\text{CO}_2\text{R}$ (25.04 ppm); 11, $-\text{CH}_2\text{CH}_2\text{CH}_3$ (22.94 ppm); 12, $-\text{CH}_2\text{CH}_3$ (14.1 ppm)

adipose tissue in rats. In animals fed fats with different fatty acid patterns (butter/lard, olive oil, sunflower oil, fish oil), clear differences were found in the in vivo spectra, consistent with a significant effect of dietary fatty acid intake on the tissue fatty acid profile. Progressively increasing the total unsaturated and polyunsaturated fatty acid content in the diet was reflected in the adipose tissue composition (Figure 2), and results were correlated with in vitro spectroscopy and gas chromatography analyses. In humans, the turnover of fatty acids in adipose tissue is slow ($T_{1/2} = 600$ d). The fatty acid profile of human subcutaneous fat therefore provides an index of the habitual dietary fatty acid intake over the previous 2–3 years.²⁰ This is of importance in long-term epidemiological surveys, but has previously been limited by the need for repeat tissue biopsies for fatty acid estimation. The application of in vivo ^{13}C NMR spectroscopy to the noninvasive analysis of adipose tissue composition is therefore of particular value for human nutritional studies.

Beckmann et al.⁸ have used in vivo ^{13}C NMR to show a significant change in human adipose tissue fatty acid composition following a fat-reduced diet, with a correlation between diet and tissue monounsaturated fatty acids. No difference was found in the degree of polyunsaturation, and this may reflect the limited 6 month period of dietary change. Bryant et al.²¹ chose to study vegan subjects as a defined population, with an established long-term diet, high in polyunsaturated fatty acids. A significantly increased adipose tissue total unsaturated and mono- and polyunsaturated fatty acid carbon content was shown in the ^{13}C spectra from the vegan group compared with omnivore controls (Figure 3). In addition, this was associated with a significant reduction in plasma concentrations of total cholesterol (4.55 ± 1.30 versus

Figure 2 Olefinic region of natural abundance in vivo $^{13}\text{C}\{^1\text{H}\}$ NMR spectra of epididymal fat pad in rats fed fats high in different fatty acids. Unsaturated fatty acid carbon resonances appear in this region: monounsaturated ($-\text{CH}=\text{CH}-$) and polyunsaturated ($-\text{CH}=\text{CHCH}_2\text{CH}=\text{CH}-$) at 129.8 ppm; polyunsaturated ($-\text{CH}=\text{CH}-\text{CH}_2\text{CH}=\text{CH}-$) at 128.2 ppm. (a) Butter/lard diet—saturated fatty acids; (b) olive oil diet—monounsaturated fatty acids [oleic acid ($\text{C}_{18:1n-9}$)]; (c) sunflower oil—polyunsaturated fatty acids [linoleic acid ($\text{C}_{18:2n-6}$)]; (d) fish oil—($n-3$) polyunsaturated fatty acids [$(\text{C}_{20:5n-3})$ and $(\text{C}_{22:6n-3})$]. In these rats, adipose tissue lipid composition measured by NMR correlates to dietary content. Increasing dietary unsaturated and polyunsaturated fatty acid content produces similar changes in the adipose tissue, shown by an increasing total signal from $\text{C}=\text{C}$ carbons and an increasing signal from polyunsaturated carbons at 128.2 ppm. Further, there appears to be a novel peak (*) at 132 ppm from unsaturated carbons at the $n-3$ position ($-\text{CH}=\text{CHCH}_2\text{CH}_3$), a double bond particularly found in the $n-3$ fatty acids of fish oil

$5.39 \pm 1.42 \text{ mmol l}^{-1}$, $p < 0.05$) and low-density lipoprotein (LDL) cholesterol (2.72 ± 1.06 versus $3.37 \pm 1.34 \text{ mmol l}^{-1}$, $p < 0.05$) in the vegan subjects. The complex interactions between lipids in plasma and the body tissues are not fully defined, but are likely to be the subject of future NMR-based, dynamic studies of nutrition and lipid metabolism.

The interaction between diet and tissue lipids has been further studied by NMR in the liver. The liver has a pivotal role in lipid metabolism. Hepatic receptor-mediated LDL clearance is a major process controlling plasma LDL concentrations, and dietary saturated fat may increase plasma LDL levels by suppression of hepatic LDL receptor activity. The mechanisms underlying this effect are unclear, but it has been suggested that enrichment of hepatic membrane lipids with saturated fatty acids interferes with LDL receptor function.²² Dietary substitution with polyunsaturated fatty acids may then increase hepatic LDL clearance and lower plasma LDL levels, possibly by increasing membrane fluidity.²³ Barnard et al.²⁴ used in vivo $^{13}\text{C}\{^1\text{H}\}$ NMR to examine the hepatic fatty acid profile in rats fed fats with different fatty acid patterns (butter/lard, sunflower oil, fish oil). The resolution of hepatic ^{13}C spectra is limited. The authors therefore used analysis by integration of signals across chemical shift ranges, and suggested expressing results by calculation of unsaturation and polyunsaturation indices (Table 1). A significant dietary effect was shown, with an increasing hepatic content of unsaturated fatty acids and an increasing degree of polyunsaturation as these fatty acids increased in the diet. However, in vitro $^{13}\text{C}\{^1\text{H}\}$ NMR studies of the liver lipid extracts showed a complex relationship,

Figure 3 Olefinic region from natural abundance in vivo coupled ^{13}C NMR spectra of human thigh adipose tissue in (a) vegan and (b) omnivore subjects. Spectra are scaled to the carboxyl signal. The vegan subjects, compared to omnivores, have an increased adipose tissue content of both total unsaturated and polyunsaturated fatty acid carbons (polyunsaturated: 3.45 ± 0.87 versus $2.39 \pm 0.55\%$ of total fatty acid carbons, $p < 0.05$). This reflects at least 3 years' adherence to the vegan diet, which, in the absence of all animal products, is high in polyunsaturated fats (polyunsaturated: 33.13 ± 7.4 versus $25.2 \pm 8.5\%$ of total dietary fatty acids, $p < 0.05$)

with evidence of hepatic metabolism of the dietary fatty acids. Indeed, the liver is a major site of fatty acid uptake, desaturation, synthesis, storage, and secretion.

Investigation of the metabolism of specific dietary fatty acids is a largely unexplored possible future application of ^{13}C NMR spectroscopy. The use of ^{13}C -labeled fatty acids to trace metabolic pathways and kinetic rates is an exciting prospect. These studies may be restricted by the limited

availability of labeled fatty acids, their oxidation after administration, and the sensitivity of the system, given the preexisting strong lipid signals. However, preliminary work has been performed by Cunnane et al.²⁵ and this demonstrated the ability of in vitro $^{13}\text{C}\{^1\text{H}\}$ NMR to detect carbon-specific incorporation of injected $[\text{U-}^{13}\text{C}]$ eicosapentaenoic acid in extracted rat liver lipids.

3.1.2 Deuterium Spectroscopy

There is considerable interest in monitoring lipid turnover in both health and disease. A novel approach to the study of dynamic in vivo tissue lipid metabolism was developed by Brereton et al.⁵ They investigated the use of in vivo ^2H NMR spectroscopy in mice. Administration of D_2O (10% v/v) in the drinking water for 3–4 d allowed the detection of deuterium-enriched tissue lipid resonances in spectra acquired in less than 2 min, as shown in Figure 4(a). The spectra consist of resonances from deuterated water (HOD) and the CHD groups of tissue lipids. Removal of D_2O from the drinking water led to clear changes in the intensity of both signals [Figure 4(b)]. The loss of deuterium from the water signal was significantly faster than from tissue lipids. The loss of deuterium from the lipid resonance was therefore proposed as a noninvasive measure of the rate of fat utilization. This method has since been applied to the study of fat utilization in obesity.

Obesity is one of the most common dietary disorders. It is characterized by excess adipose tissue and elevated levels of plasma nonesterified fatty acids. Furthermore, obesity is known to lead to glucose intolerance and insulin resistance. Fat turnover, as reflected by the levels of plasma nonesterified fatty acids, has been suggested as being implicated in this process. However, the lack of in vivo techniques for measuring fat utilization has greatly hampered progress in this area. Body fat turnover in mouse models of obesity and diabetes mellitus have been studied in vivo using the ^2H NMR technique.²⁶ Brereton et al.²⁶ showed that the rates of fat utilization in obese mice were significantly lower than the rates for nonobese mice (Figure 5) and the induction of diabetes did not affect utilization of fat as a metabolic fuel.

These studies clearly suggest that deuterium NMR spectroscopy provides researchers with a powerful method for noninvasively assessing fat turnover rates.

3.1.3 Proton Spectroscopy

The application of in vivo proton NMR spectroscopy to dietary studies has been rather limited. Indeed, many of the

Table 1 Hepatic Fatty Acid Profile by In Vivo $^{13}\text{C}\{^1\text{H}\}$ NMR Spectroscopy of Rats Fed Different Fats

Dietary Fat	Unsaturation Index ^a	Polyunsaturation Index ^b	Methylene–Methyl/% ^c	Olefinic/% ^c
Butter/lard	0.19 ± 0.04	0.90 ± 0.04	84.1 ± 0.91	15.9 ± 0.91
Sunflower oil	0.24 ± 0.01	1.04 ± 0.04	80.9 ± 0.31	19.1 ± 0.31
Fish oil	0.27 ± 0.01	1.32 ± 0.03	78.9 ± 0.79	21.1 ± 0.79

$p < 0.05$ for all differences between dietary groups.

^aUnsaturation index = olefinic/methylene–methyl signal integration (measures the ratio of unsaturated to saturated fatty acid carbons).

^bPolyunsaturation index = signal intensity at 128.2 ppm ($=\text{C}-\text{C}=\text{C}=\text{C}$)/129.8 ppm ($-\text{C}=\text{C}-$) (measures the ratio of polyunsaturated to monounsaturated + polyunsaturated carbons).

^cOlefinic and methylene–methyl signal area as the percentage of the total fatty acid signal integration (measures the percentage of fatty acid carbons that are unsaturated or saturated, respectively).

Figure 4 (a) Natural abundance ^2H NMR spectrum of a mouse. The CHD resonance is to high field at 1 ppm. Chemical shifts were referenced to the HOD resonance assigned to 4.8 ppm. (b) Deuterium NMR spectra of a mouse following the removal of 10% (v/v) of D_2O from its drinking water. The spectra were recorded (a) 1, (b) 4, (c) 5, (d) 8, (e) 11, (f) 15, (g) 16 and (h) 21 days after the resumption of normal drinking water. Spectrum (i) was recorded prior to the administration of D_2O to the drinking water (Adapted with permission of Heyden & Son Limited from I. M. Brereton, D. M. Doddrell, S. M. Oakenfull, D. Moss, and M. G. Irving, *NMR in Biomed.*, 1989, **2**, 55)

metabolites observed by ^1H NMR spectroscopy do not appear to be affected by diet, with the exception of lipids.⁷ However, due to the small chemical shift range of ^1H resonances and the intense water signal, in vivo ^1H lipid studies have also been restricted. A potentially important alternative application of ^1H NMR is the use of fat imaging to determine quantitative fat distribution in human subjects.²⁷ Regional fat distribution has been correlated to serum lipids and coronary heart disease. Existing methods for measurement of body fat distribution are limited, and fat imaging may in future become the modality of

Figure 5 Plots of ^2H NMR signal intensity as a function of time showing (a) best fit single exponential decay curves for HOD and (b) best fit biexponential function for CHD intensities. The experimental data for control (solid square) and obese (solid circle) mice were used to calculate the body water and fat utilization rates. choice in nutritional and metabolic studies evaluating the risk of coronary heart disease.

3.2 Glycogen Studies

Tissue glycogen values may be a marker of carbohydrate intake and could therefore be of value in dietary studies. Shulman and co-workers²⁸ have developed a ^{13}C NMR technique to provide a direct noninvasive method to measure liver and muscle glycogen concentration in humans. The time course of liver glycogen concentration, following standard test meals, has been carried out by ^{13}C NMR spectroscopy. This opens the possibility of following quantitative changes in glycogen storage with varying diets.^{29,30}

4 HIGH-RESOLUTION NMR SPECTROSCOPY

The unique exploratory capability of NMR spectroscopy has been utilized to investigate the effects of diet on the metabolic profile of body fluids.³¹ The ^1H NMR spectra of urine from

Figure 6 Proton NMR spectra at 500 MHz (aliphatic regions) of urine from 1-month-old rats fed either (a) chow or (b) casein diets. Assignments: Lac, lactate; Ac, acetate; NAc, *N*-acetyl groups of glycoproteins; Suc, succinate; Og, 2-oxoglutarate; Cit, citrate; Dma; dimethylamine; Dmg, dimethylglycine; Cr, creatinine; Cn, creatine; Tau, taurine; NMe, betaine plus trimethylamine *N*-oxide. (Reproduced by permission of Academic Press, Inc. from J. D. Bell, O. Lavender, V. C. Morris, and P. J. Sadler, *Magn. Reson. Med.* 1991, **17**, 414)

rats fed different diets are shown in Figure 6. Clear changes in the metabolic profile of the urine can be observed.¹⁰ Rats fed casein diets for 1 month postweaning did not excrete 2-oxoglutarate, and excreted lower levels of hippurate, succinate, and citrate compared with age/sex-matched rats fed standard chow diets. The acquisition of these spectra took ~2 min. This suggests that high-resolution NMR of urine or other body fluids could be utilized as a fast, multicomponent technique in human studies, for example to screen rapidly for multiple metabolic effects or to check dietary compliance.

Plasma concentrations of LDLs and high-density lipoproteins (HDLs) are well established markers for coronary heart disease risk assessment. Standard methods for quantification and compositional analysis of plasma lipoproteins require laborious and time-consuming physical separation based on particle size, density, or apolipoprotein content. Bell et al. have shown that NMR spectroscopy can be readily applied to study alterations in plasma lipoproteins associated with dietary manipulation, both in intact plasma or in the separated lipoprotein classes.^{11,12} The effects of fish oil supplementation on the ¹H NMR profile of lipoproteins in intact plasma are illustrated in Figure 7. Changes in composition are shown by a new lipid resonance (peak 2A) arising from fish oil $n - 3/\omega - 3$ fatty acids incorporated into plasma lipoproteins, while the methylene $[-(\text{CH}_2)_n-]$ signal (peak 3) is markedly reduced. Furthermore, T_2 analysis of the lipid resonances showed that these changes in lipid composition of the LDL particles are accompanied by alteration in the structural characteristics of these particles.

Figure 7 Expansions of spin echo ¹H NMR spectra of intact human plasma (a) before and (b) after 7 d of fish oil supplementation. Assignments: peaks 1 and 2, terminal $-\text{CH}_3$ group from LDLs/HDLs and very low-density lipoproteins (VLDLs), respectively; peak 3, $-(\text{CH}_2)_n-$ of VLDLs. Peak 2A arises from $n - 3/\omega - 3$ fatty acids incorporated into plasma lipoproteins. (Reproduced by permission of Birkhauser Verlag from P. C. Dagnelie, J. D. Bell, M. L. Barnard, and S. C. R. Williams, in 'Omega-3 Fatty Acids: Metabolism and Biological Effects' ed. C. A. Drevon, I. Baksaas, and H. E. Krokan, Birkhauser Verlag, Basel/Switzerland, 1993, p. 27–34)

At present, sophisticated computer deconvolution methods (line-fitting analysis) are being developed to identify and quantify lipoprotein fractions in the ¹H NMR spectra of intact plasma samples (500 μl) within minutes.^{32,33}

In this article we have reviewed the current state of NMR spectroscopy as applied to dietary studies. It is clear that this is a relatively new area of NMR research. However, it offers many exciting prospects for future research into diet and nutrition in humans.

1 BACKGROUND: BIOCHEMISTRY OF COMA

Metabolic disturbances of liver, kidney, endocrine or other systems have remote effects; those on the brain result in a variety of well defined encephalopathies. When severe, these disorders present as coma. Posner and Plum published a comprehensive account of human coma.¹ Many were the result of presumed metabolic events with normal brain anatomy, setting the stage for noninvasive elucidation by means of biochemically based techniques. Among these are MRA, diffusion imaging, positron emission tomography (PET), single-photon emission tomography (SPECT), and multinuclear magnetic resonance spectroscopy (MRS). MRS has increasingly been used to identify specific biochemical changes in the brain, from which information on diagnosis and pathogenesis of these poorly understood disorders is beginning to emerge.

As a model for this group of disorders, we discuss hepatic encephalopathy, with additional remarks about diabetic, hyperosmolar, and hypoxia-induced encephalopathies.

2 NEUROCHEMICAL PATHOLOGY OF HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy (HE) is an excellent example of metabolic encephalopathy,² with identifiable neurotoxins

originating in a systemic disease. In animal studies, several distinct neurotoxins have been identified. The earliest of these was ammonia;^{3,4} ammonia is normally fully removed from portal blood by hepatic urea synthesis.^{5,6} The combination of the loss of biosynthetic liver function and the diversion of nondetoxified blood to the brain by so-called portal systemic shunts (PSSs) accounts for the frequently demonstrated excess of cerebral and cerebrospinal fluid glutamine⁷ [equation (1)].

The enzyme glutamine synthetase (GS) responsible for this reaction is located exclusively in astrocytes.⁸ Resynthesis of glutamate and of γ -aminobutyrate (GABA) from glutamine (both vital neurotransmitter amino acids) occurs principally in neurons.⁹

Lest it be thought that ammonia 'toxicity' accounts for all of the clinical syndromes covered by the term HE, the interested reader is referred to Butterworth¹⁰ for an extensive review of several other well-documented alternatives. Metabolic theories abound: failure of oxidative energy metabolism (a corollary of glutamate and 2-oxoglutarate depletion from the Krebs cycle), tryptophan and serotonin (5-hydroxytryptamine) accumulation, branched-chain amino acid deficits, endogenous benzodiazepine agonists which modify access of GABA to its inhibitory receptors, and neurotoxic fatty acids, octanoate in particular, have been proposed.

An attractive unifying theory proposed by Zieve¹¹ is that multiple neurotoxins derived from liver, blood, or from the diet, gain access via PSSs to a previously 'sensitized' brain. No mechanism of sensitization is known, but with the advent of MRS, a candidate has been proposed in the form of cerebral *myo*-inositol depletion.¹²

3 ANIMAL STUDIES IN HE USING MULTINUCLEAR MR SPECTROSCOPY

Three groups^{13–15} independently perfected methods for the noninvasive determination of cerebral glutamine (including a variable contribution from glutamate in each assay) with ¹H NMR spectroscopy (now referred to as MRS) and confirmed the elevation of this metabolite in a variety of animal models of acute liver 'failure' with HE. One of these groups¹³ also demonstrated a hitherto unrecognized abnormality, the significant reduction of choline (Cho; cerebral choline-containing compounds) in the ¹H spectra of rats with acute HE. More recently, ¹⁵N NMR^{16,17} and ¹H–¹⁵N HMQC (unpublished work from this laboratory) identified cerebral glutamine unequivocally in vivo in HE produced by ammonia infusion in the normal and portocaval shunted rat, respectively.

Finally, in extracts of portocaval shunt (PCS) rat brain, high-performance liquid chromatography confirms the accumulation of glutamine and the depletion of glycerophosphoryl choline (GPC, which is therefore the explanation for the reduced 'Cho' in the previous ¹H NMR study), as well as demonstrating the expected depletion by 50% or more, of the cerebral *myo*-inositol (mI) and *scyllo*-inositol (sI) content.¹⁸ This result in rats confirmed the observations which first emerged from human studies with short echo time ¹H MRS,^{12,19,20} and establishes the validity of the portocaval shunt rat for future experimental studies.

4 PATHOGENESIS, DIAGNOSIS, AND THERAPEUTIC MANAGEMENT OF HE IN MAN: THE EMERGING ROLE OF PROTON MRS

Studies using STEAM localized, short echo time ^1H MRS defined the changes in 10 patients with clinically confirmed chronic HE. The average increase in cerebral glutamine was estimated as +50%, Cho decreased 14% and mI decreased by 45%²¹ (Figure 1). Very similar findings have now been reported at 2T by Bruhn^{19,22} and by McConnell²³ using PRESS at short or long echo times. An early study which used long echo time PRESS-localized ^1H MRS failed to identify the depletion of mI, but was the first clearly to show 'Cho' depletion in human brain.²⁴

Figure 1 Development of hepatic encephalopathy in human subjects (1.5T spectra). A series of spectra of parietal cortex (white matter) acquired under closely similar conditions (GE Signa 1.5T, STEAM localization TR 1.5 s, TE 30 ms, NEX 128) from different patients is presented. A normal spectrum for comparison is that in Figure 6(b). In liver disease (top) there is a relatively normal spectrum with a slight decrease in choline. In subclinical hepatic encephalopathy (SCHE) there is a definite decrease in *myo*-inositol (mI) with a minor increase in the glutamine regions (glutamine plus glutamate = Glx). There is a very significant increase in the Glx regions in HE (grade 1) and mI is further depleted. The spectrum of grade 3 HE shows more severe changes in the biochemical markers of this disease, most notably glutamine

5 ENERGETICS OF THE HUMAN BRAIN IN HE

The predicted cerebral energy deficit (reduction in [ATP]) has convincingly only been shown in mice and tree shrews.²⁵ Phosphorus-31 MRS should be the easiest tool with which to establish any energy deficit in HE (as predicted). Ross,²⁶ Tropp,²⁷ Chamuleau,²⁸ Barbiroli,²⁹ and Morgan³⁰ have obtained conflicting and hence unconvincing data with ^{31}P MRS on such effects in man. Using quantitative ^1H MRS, however, Geissler and colleagues showed a small but significant increase in cerebral creatine concentration [Cr] following liver transplantation in man.³¹ Since [Cr] is the sum of phosphocreatine (PCr) and creatine, this may indicate that patients with HE have an 'energy deficit'. The difficulty which has been confronted in demonstrating such an effect by ^{31}P MRS, where sensitivity is 10% that of ^1H MRS, becomes obvious. Since reduced cerebral oxygen consumption and blood flow are recognized abnormalities in HE, the ^{13}C NMR techniques pioneered by Shulman may be best suited to demonstrate the anticipated reduction in the overall rate of the Krebs cycle.³²

From these clinical studies, it appears that ^1H MRS, particularly if applied with effective water suppression to reveal mI, is currently most efficient for the elucidation of pathogenesis of HE, and also, as will be shown, for its early clinical diagnosis. Direct measurement of mI by ^{13}C NMR may become a valuable adjunct.³³

6 SUBCLINICAL HE

As indicated, HE is a group of diseases presumed to have identical etiology, but presenting a great variety of distinct clinical pictures. Underlying all of them is believed to be the entity of 'subclinical HE', although it is by no means clear

Figure 2 Identification of glutamine in the proton spectra at 2.0T. A 51-year-old patient with HE due to surgical portacaval shunt (b) is compared with a normal control (a). Spectra were obtained from an occipital GM location and show the expected changes of HE: increased glutamine, decreased Cho/Cr and mI/Cr. With the improved resolution at 2T, separate analysis of glutamine and glutamate is possible. Inset are spectra from model solutions (c) 5 mM glutamate + 5 mM NAA; (d) 5 mM glutamine + 5 mM glutamate + 5 mM NAA, indicating that in this patient the increase in glutamine occurs without obvious depletion of cerebral glutamate. Spectra were acquired on a Siemens 2.0T clinical spectrometer, with STEAM localization; TR 3 s, TE 20 ms. (Modified from Bruhn et al.)²²

Figure 3 Proton MRS in acute hepatic encephalopathy due to Reye's syndrome. In vivo proton MRS spectra acquired from a parietal white matter region in infant brain from: (a) 10-month-old normal subject; (b) patient, day 2 after admission; (c) patient, day 8 after admission; (d) difference (b)–(c) between days 2 and 8 in patient; (e) solution with 15mM glutamine. All spectra are scaled. Spectral assignments: Lac, lactate (1.3 ppm); NAA, *N*-acetylaspartate (2.02 ppm); Gln, glutamine (2.10–2.50 ppm, and 3.65–3.90 ppm); Cr + PCr, creatine + phosphocreatine (3.03 ppm); Cho, choline containing compounds (3.23 ppm); mI, *myo*-inositol (3.56 ppm). U, Unassigned (3.62 ppm). Notable abnormalities concern a huge accumulation of cerebral glutamine, reduced Cho, and, later, reduced mI, all of which reflect liver failure. In addition there is a decrease in NAA and [Cr] and appearance of the unassigned peak. Reye's syndrome, a toxic viral disease associated with aspirin intake is known to produce severe neuronal damage, and may not therefore completely correspond to the picture of acute liver failure. An occipital grey matter region gave almost identical results. (Reproduced with permission from Ernst et al.)³⁶

that the HE and coma of fulminant (very acute) liver failure, goes through any truly 'subclinical' phase.

Proton MRS accurately reflects the entity of SCHE,^{34,35} and in preliminary studies also appears to mirror the progressive and increasingly severe syndromes of overt HE defined by Parsons-Smith as grades 1–4 (Figure 1). Elevation of

glutamine is rather more obvious at 2 T (Figure 2), but presents little difficulty at 1.5 T.

Figure 1 should not be taken as proof, however, that in the individual patient such orderly progression of neurochemical dysfunction occurs. Longitudinal studies have not been performed in sufficient numbers to be certain of this. Nevertheless, it is tempting to suggest, as Figure 1 appears to indicate, that in the brain exposed to liver 'toxins', Cho depletion (possibly GPC) precedes the loss of mI and sI, with later accumulation of glutamine. If this sequence is correct, then perhaps 'sensitization' of the brain is the result of mI or Cho depletion, or both. In keeping with the theory of many years standing, increasing cerebral glutamine underlies the neurological syndromes of grades 1–4, severe, overt chronic HE, as well as, perhaps, that of acute, fulminant HE and coma. Figure 3 shows the similar but more severe neurochemical changes of Reye's syndrome, giving an effective indication of what may be seen in acute HE.³⁶ Unfortunately, published spectra from patients with fulminant HE are limited and difficult to interpret.³⁷

7 mI DEPLETION AND THE INDUCTION OF HE

A human 'experiment' which goes some way towards verifying this sequence is the new interventional procedure known as

Figure 4 Effect of TIPS on the proton MR spectrum. Spectra are from a 30-year-old female, 5 days after a hematemesis due to esophageal varices and chronic alcoholic liver disease. Spectra acquired from a parietal WM location (GE Signa 1.5 T, volume 12.5 cm³, STEAM TR 1.5 s TE 30 ms, NEX 128) before a TIPS procedure shows no abnormalities apart from a small but significant reduction in Cho/Cr, attributable to liver disease (top). Three weeks after TIPS, changes are seen in the Glx and mI regions and a further reduction on Cho/Cr (middle). The bottom spectrum shows the progression of changes seen (13 weeks post-TIPS); Glx is markedly increased and mI is significantly reduced

TIPS (transjugular intrahepatic portal systemic shunt), which is used as a life-saving procedure in cirrhosis-induced hematemesis. Not surprisingly, TIPS induces clinical HE in up to 90% of survivors.^{38,39} Proton MRS performed both before and after TIPS in 10 patients showed a universal increase in mean intracerebral glutamine following the procedure. More importantly, in a small number of individuals in whom mI was normal prior to TIPS (these patients often show subclinical HE), a progressive reduction in mI/Cr and development of subclinical and clinical HE follows the introduction of the shunt (Figure 4).

8 RESTORATION OF CEREBRAL mI AND CHO ACCOMPANIES REVERSAL OF HE

Yet another common human ‘experiment’, that of orthotopic liver transplantation, allows the reverse process to be unequivocally demonstrated, thereby establishing a firm, albeit circumstantial link between mI depletion and the syndromes of subclinical and overt HE (Figure 5). Glutamine plus glutamate and Cho also recovered. Indeed, an overshoot of cerebral Cho is consistently observed, perhaps linking the earlier Cho depletion with deficient hepatic biosynthesis of some relevant precursor of GPC.

9 ORNITHINE TRANSCARBAMYLASE (OTC) DEFICIENCY

A description of MRS in HE would be incomplete without consideration of a rare but informative inborn error

Figure 5 Restoration of biochemical abnormalities post-liver transplant. The patient is a 30-year-old male with acute-on-chronic hepatic encephalopathy secondary to hepatitis, and subsequently successfully treated by liver transplantation. Spectra were acquired 6 months apart from the same parietal WM location, (15.0 cm³ STEAM TR 1.5 s, TR 30 ms, NEX 128) and scaled to the same Cr intensity for comparison. The obvious abnormalities before liver transplantation, increased α , β , and γ glutamine, reduced Cho/Cr and mI/Cr (upper spectrum) were completely reversed 3 months after transplantation, and Cho/Cr exceeded normal (lower spectrum)

Figure 6 Treated OTC deficiency versus healthy age-matched subject. Both spectra were acquired from a similar location in parietal WM (STEAM TR 1.5 s, TE 30 ms, NEX 128) and processed as described in the literature⁴⁶. Single-enzyme defects in the urea cycle result in severe hyperammonemia and ‘hepatic encephalopathy’. Because the patient was receiving treatment with sodium benzoate, no excess of cerebral glutamine is present. However, as anticipated by studies in the commoner condition of hepatic encephalopathy due to portosystemic shunting, a decrease in mI was noted in the proton spectrum of a 14 year-old with OTC deficiency (a) when compared with a normal age-matched control (b)

of hepatic urea synthesis, ornithine transcarbamylase (OTC) deficiency. The single known biochemical consequence is hyperammonemia. Gadian and colleagues³⁷ demonstrated the inevitable elevation of cerebral glutamine in two such patients, while Ross⁴⁰ showed the extraordinary parallel with HE, in depletion of cerebral mI (Figure 6).

10 CONTRIBUTION OF NMR TO CLINICAL HE

10.1 Pathogenesis of HE

Both experimentally and clinically, NMR (particularly ¹H MRS) supports the classical concept of HE as a disorder of cerebral ammonia metabolism, be it by ammonia toxicity or glutamine synthesis (as a newer variant of the theory would have it).⁴¹ The concept of an underlying brain ‘sensitization’ receives substantial new impetus deserving of further research in animal models. Either ‘Cho’ (GPC) depletion, due perhaps to failure of hepatic synthesis of a necessary precursor, or cerebral mI depletion could fulfill the role of ‘sensitizer’. In neither case is there a precedent, so that basic research is

urgently required. It is likely that NMR will play a crucial role in such investigations, and the PCS rat is a convenient model. Carbon-13 NMR is the only method of unequivocally determining mI as distinct from the lower concentrations of inositol-1-phosphate (Inos-1-P) and glycine with which mI coresonates in the ^1H MR spectrum.

10.2 Proton MRS for Diagnosis

Early in these investigations, it became apparent that mI depletion and Glx accumulation occurred when clinical HE was absent. Other systemic or metabolic diseases (apart from OTC deficiency already discussed) did not result in mI depletion, so that ^1H MRS offers an unique opportunity for early, specific diagnosis of this still perplexing condition. Paradoxically, there is at present little enthusiasm for this, most probably because prevention (with lactulose or neomycin) and treatment (by liver transplantation) of overt or severe HE is relatively straightforward (albeit rather costly in the case of orthotopic liver transplantation (OLT) at \$150 000–200 000 per patient in USA). If a ready medical means of restoring cerebral mI were to be discovered, the value of ^1H MRS in diagnosis might increase.

10.3 Unanswered Questions in Neurology of HE

Wilson's disease, caused by excess copper deposition, is believed to result in an encephalopathy analogous to HE. However, the ^1H MRS findings are not surprisingly rather different, lacking either mI depletion or glutamine accumulation (unpublished study from this laboratory).

Myelopathy is an unusual form of chronic HE. It presents with myelopathy and paraplegia. Although neurological considerations would suggest cord involvement, the ^1H MRS findings in the parietal cortex are typical of other patients with the more classical clinical presentation (see Fig. 4 in Ross et al.).⁴⁰

Often noted in MRI, the basal ganglia may be 'bright' in inversion recovery (IR) images of patients with known HE. There is no consistent relationship with ^1H MRS findings, and increasingly this MRS finding is recognized as nonspecific. Nevertheless, the extrapyramidal signs, the changes on postmortem, and these albeit inconsistent MRI findings continue to suggest that there may be as yet unrecognized underlying neurochemical changes in the basal ganglia in HE.

11 OTHER SYSTEMIC ENCEPHALOPATHIES

11.1 Diabetes Mellitus

Like HE, diabetic encephalopathy is common and obviously 'metabolic' in origin. Three principal syndromes are recognized: diabetic ketoacidosis, lacticidosis, and nonketotic hyperosmolar coma.

Elevated cerebral glucose,⁴² significant excess of mI, a reversible accumulation of 'Cho', and the presence of ketone bodies have been detected in various patients with varying severity of diabetic encephalopathy.⁴³

Figure 7 Diabetic ketoacidosis (DKA): cerebral ^1H spectra during two DKA episodes and recovery. (a) Episode 1, acquired 3 days after admission to hospital, at a time when the patient had supposedly totally recovered and was ready to be discharged. A peak characteristic for the presence of ketone (K) bodies was noted at 2.22 ppm, obtained from an 18 cm^3 volume in the left parietal lobe. The patient relapsed into DKA 2 days later. (b) Episode 2, acquired 5 months later from an occipital gray matter location (10.3 cm^3) during a second episode of DKA. In addition to the ketone peak, peaks for glucose (G) were seen. (c) Recovery, 6 days after episode 2 (from the same occipital location), when no more ketone bodies were detected in the urine. (d) Occipital cortex of an age- and sex-matched healthy subject. Acquisition conditions: GE Signa 1.5 T, 4X software; STEAM TR 1.5 s, TE 30 ms, NEX 128. More detailed analysis of peak K indicates the resonance frequency to be that of acetone, rather than acetoacetate, the ketone body more commonly identified in blood and urine of diabetics in coma. (Reproduced by permission of the Radiological Society of North America from Kreis and Ross)⁴³

The most surprising finding of proton MRS which requires further study is the identification of acetone (rather than the more widely anticipated β -hydroxybutyrate and acetoacetate) as the ketone of human diabetic ketoacidotic encephalopathy⁴³ (Figure 7).

Long-term neurological and cerebral 'complications' of diabetes contribute to the much increased mortality. The biochemical basis of these conditions may lie in those changes in Cho, N-acetylaspartate (NAA), mI, ketones, and glucose, now recognized by ^{13}C and ^1H MRS, to be present in the acutely and chronically diabetic brain.

11.2 The Hyperosmolar State: Identification of Idiogenic Organic Osmolytes by Proton MRS

Lien et al. first used ^1H MRS to investigate a 'new' family of cerebral metabolites collectively known as organic osmolytes, because of their believed role in the maintenance of cerebral osmotic equilibrium.⁴⁴ Such molecules were also first thoroughly researched in the papilla of the kidney with the help of in vitro NMR.⁴⁵

Figure 8 Time course of changes in principal cerebral organic osmolytes during correction of severe dehydration. A series of spectra were obtained from the same (occipital gray matter) brain location, in a 14-month-old child, recovering from severe dehydration and hypernatremia (plasma sodium 195 mEq l^{-1} ; normal range $135\text{--}142 \text{ mEq l}^{-1}$) using identical acquisition conditions. Spectra were processed and scaled identically to permit subtraction of sequential spectra (difference spectroscopy). The day of examination refers to interval since admission to hospital. Examinations are numbered sequentially, from the first (Exam. 1) to last (Exam. 5) on day 36. Compared with a relevant normal [spectrum (b), Figure 6], the principal abnormality appears to be a reversal of the intensities of NAA (reduced) and mI (increased), so that mI dominates the spectrum. These changes slowly reverse to be nearly normal on day 36. The resultant difference spectra more clearly identify the progressively falling concentrations of several metabolites, with a possible elevation in the resonance peak assigned to the neuronal marker NAA. Quantitative MRS defines the principal abnormality as a threefold increase in the concentration of the cerebral osmolyte

First in sporadic cases of diabetic hyperosmolar coma⁴³ and in a patient after closed head injury,⁴⁶ and then most convincingly in a single infant with holoprosencephaly and deficient thirst mechanisms, these concepts were confirmed as contributing to human encephalopathy by the use of ^1H MRS (Figure 8). mI was three times normal, and other resonances, also markedly affected, returned toward normal with treatment. Difference spectroscopy is particularly helpful in identifying these changes.^{47,48} The converse, or hypoosmolar state of hyponatremia has been identified by ^1H MRS in significant numbers of patients.⁴⁹

11.3 Hypoxic Encephalopathy

The prime example of a systemically induced encephalopathy is that due to insufficient oxygenation of blood, with resultant failure of cerebral oxygen delivery. Hypoxic encephalopathy is best understood in the context of energy failure and altered redox state through all cerebral metabolic pathways. Loss of ATP and PCr, accumulation of ADP, AMP,

inorganic phosphate, and Cr are obvious consequences; H^+ accumulates, both due to failure of removal of CO_2 and formation of lactate. Reduced partners of the equilibrium enzymes, lactate and glutamate dehydrogenase, accumulate. In practice, glutamate is probably equally rapidly converted to glutamine. Innumerable animal studies, using principally ^{31}P NMR, but also ^1H NMR, confirm these principles and document other previously unsuspected changes, notably the loss of NAA.

The very common occurrence of hypoxic encephalopathy in humans has given ample opportunity for verification of these events in the human brain. 'Recovery' from nonlethal hypoxic encephalopathy gives yet another view of the metabolic process. From ^{31}P MRS in neonates,⁵⁰ the expected changes emerged.

More recently, ^1H MRS has been used to quantify and plot the time course of changes which occur after oxygen deprivation, applying the information to defining the degree of irreversible hypoxic neuronal damage—and hence prognosis. 'Near-drowning' is the term applied when virtually total oxygen deprivation occurs, due to submersion in water. It must be presumed that all ATP and PCr is lost, and all glucose

Figure 9 Near-drowning with fatal outcome. Brain spectrum from occipital cortex of a severe near-drowning victim (3 years old), examined 48 hours post-immersion (top), and the glutamine standard (bottom). The patient died on the 5th day post-injury. The ^1H spectrum was acquired from a volume of 12 cm^3 (STEAM TR 3.0 s, TE 30 ms, data processing including correction for residual water, line fitting, and quantification as described by Kreis et al.).⁴⁶ The spectrum of the glutamine standard (10 mM) was acquired in the same way, and scaled appropriately. Notable abnormalities in the patient spectrum are the very much reduced NAA/Cr ratio (and [NAA] concentration), excess of lactate (doublet at 1.3 ppm), and of the strongly coupled resonances of α , β , and γ glutamine protons. A 25% reduction in [Cr] was apparent on quantitative examination. (Thanks to Dr. Roland Kreis, Thomas Ernst, and Edgardo Arcinue MD)

converts to lactate in this period of anoxia. Yet at the first clinical examinations, 24 hours after rescue and artificial life support, MRS demonstrates more often than not the absence of lactate, normal Cr (plus PCr), and NAA at nearly full concentration. Only subsequently do NAA and total Cr fall and lactate appear. The severity of the changes gives a fairly good guide to outcome.⁵¹

The classic events of anoxia described by Lowry⁵² are probably reversible, but secondary damage results in progressive cell death, the consequences of which are loss of NAA (in the case of dying neurons), loss of PCr and oxidative function and reaccumulation of lactate. It is unclear why the large accumulations of glutamine occur, or what the consequences are for survival (Figure 9).

12 CONCLUSIONS

Diffuse metabolic changes in brain biochemistry are the result of complex interactions of disordered biochemistry in many other organs and tissues. Hepatic encephalopathies, diabetic coma and hyperosmolar states and hypoxic encephalopathy are examples of such conditions in which accurate application of quantitative NMR spectroscopy sheds new light. Diagnostic utility of MRS in metabolic encephalopathies will increase as new therapeutic options are developed.

In Vivo Hepatic MRS of Humans

Isobel Jane Cox

Imperial College School of Medicine, London, UK

1 INTRODUCTION

The liver is the largest organ in the human body. By virtue of its anatomical position, the liver is readily suited to study by *in vivo* magnetic resonance spectroscopy (MRS) (*Whole Body Studies: Impact of MRS*). The liver is the principal homeostatic organ in the body, being responsible for the metabolism of carbohydrates, fats, and circulating proteins and the detoxification of the body's waste products. It is the most important site for the metabolism of drugs and alcohol. Bile is produced in the liver, which is important for the digestion of fats in the gut and which also acts as a transport medium for the excretion of bilirubin and certain drugs. Information about a number of these processes can be obtained by multinuclear MRS study. For example, the phosphorus spectrum provides an assessment of hepatic energy state, membrane turnover, levels of endoplasmic reticulum and glycolytic/gluconeogenic intermediates. Signals from glycogen and lipids can be measured using natural abundance ^{13}C MRS. Fluorine-19 MRS can be used to detect metabolites of fluorinated drugs. Proton MRS provides a measure of hepatic water and fat content, but it has proved very difficult to obtain a metabolite spectrum because of the effects of respiratory motion. Clinical hepatic MRS builds on experience from the study of cell lines (see *Cells and Cell Systems MRS*) and animal models (see *Animal Methods in MRS*). The majority of human applications to date have used ^{31}P MRS as this is technically the easiest, and the data obtained have been used to aid diagnoses, monitor treatment effects, and to study hepatic biochemistry.

2 THE NORMAL LIVER SPECTRUM

2.1 Phosphorus-31 MRS

The phosphorus liver spectrum from a healthy adult volunteer comprises six major peaks, assigned to phosphomonoesters (PMEs), inorganic phosphate (Pi), phosphodiester (PDEs) and the three phosphate groups (α , β , and γ) in nucleotide triphosphates (NTPs) (Figure 1). Notably absent from this spectrum are signals from membrane phospholipids such as phosphatidylcholine. The phosphorus nuclei in such large molecules have reduced mobility and the signals are NMR invisible. Similarly, the signal from adenosine diphosphate (ADP) bound to proteins is not detectable using NMR methods, and therefore the small ADP signal observed only represents free ADP.

2.1.1 The Phosphomonoester Resonance

The peak assigned to phosphomonoesters (PMEs) contains at least 10 components,¹ including: glucose 6-phosphate (G6P), glycerol 3-phosphate (G3P), glycerol 1-phosphate (α PG), and ribose 5-phosphate, which are intermediates in carbohydrate metabolism; coenzyme A, which is important in the metabolism of fatty acyl moieties; phosphoethanolamine (PE) and phosphocholine (PCh), which are metabolites on the pathway of membrane synthesis; adenosine monophosphate (AMP), which is an intermediate of adenosine triphosphate (ATP) and ADP turnover; and 2,3-diphosphoglycerate (2,3-DPG) which is present in blood, although it is unclear how much 2,3-DPG in circulating blood contributes to the *in vivo* spectrum.

2.1.2 The Inorganic Phosphate Resonance

The Pi signal is thought to represent about 40% of intracellular levels of Pi.² It is unclear why the remainder is invisible, but may be bound in the mitochondria. Pi, together with ATP and ADP, play a key role in energy metabolism, and changes in hepatic energy state may therefore be reflected by an alteration in the ATP/Pi ratio. The chemical shift of Pi in liver cells is dependent on pH, and cytosolic pH has been measured to be 7.18 ± 0.03 in perfused rat liver using micro-electrodes.³ In humans, the pH has been found to be consistent with this, and examples of values from healthy adult volunteers are: 7.18 ± 0.08 ,⁴ 7.32 ± 0.02 ,⁵ 7.36 ± 0.23 ,⁶ and 7.23 ± 0.14 .⁷

Figure 1 Proton decoupled localized ^{31}P NMR spectrum of the human liver, obtained at 1.5 T, using a 14 cm diameter surface coil. The localization scheme was ISIS with frequency modulated inversion and excitation pulses. The spectrum was obtained in 280 scans with 3 s repetition time. Proton decoupling has improved resolution in the phosphodiester, phosphomonoester, and diphosphodiester regions. Well-resolved resonances are observed for glycerophosphoethanolamine (GPE), glycerophosphocholine (GPC), and phosphocholine (PCh). DPDE, diphosphodiester. (Reproduced by permission of Heydon & Son from P. R. Luyten, G. Bruntink, F. M. Sloff, J. W. A. H. Vermeulen, J. I. van der Heijden, J. A. den Hollander, and A. Heerschap, *NMR Biomed.*, 1989, **4**, 177)

2.1.3 The Phosphodiester Resonance

The phosphodiester (PDE) signal contains contributions from at least three water-soluble metabolites,¹ including glycerophosphoethanolamine (GPE) and glycerophosphocholine (GPC). GPE and GPC are intermediates in phospholipid catabolism. At the field strengths used for clinical studies, a broad, field-dependent signal has also been identified, which has been assigned to phospholipid bilayer, including endoplasmic reticulum, with a small contribution from motionally averaged macromolecules.^{8,9} In addition, phosphoenolpyruvate (PEP), although not a PDE, resonates in this region.

2.1.4 The Nucleotide Triphosphate Resonances

The dominant contribution to the nucleotide triphosphate (NTP) peaks are from ATP, but 10–20% of the peak area may be due to guanosine triphosphate (GTP) and uridine triphosphate (UTP). Further signals can be identified, overlapping with peaks from the three phosphate groups. For example, the α NTP resonance overlaps with signals from α ADP and nicotinamide adenosine dinucleotide (NAD) or its reduced form (NADH). The γ NTP signal overlaps with signals from β ADP. It is interesting that the majority of ADP is NMR invisible, as discussed above. NAD and NADH play a pivotal role in electron transport in redox reactions, but it remains unclear what proportion is bound to proteins and is therefore not detected by *in vivo* MRS.

Binding to magnesium affects the chemical shifts of ATP, and therefore ³¹P MRS provides information about the ratio of free ATP to magnesium-bound ATP.⁴ This, in turn, reflects the intracellular concentration of free magnesium.¹⁰ Oberhaensli et al.⁴ measured the separation of β ATP and γ ATP to be 13.70 ± 0.07 ppm, and estimated that 86% of the cytosolic ATP pool was magnesium bound, corresponding to a free cytosolic magnesium concentration of approximately $300 \mu\text{mol L}^{-1}$. This result is consistent with the estimated free magnesium concentration of $450 \mu\text{mol L}^{-1}$ in the perfused rat liver.¹¹

2.1.5 Age-Related Changes

The hepatic phosphorus spectrum from neonates and infants differs from the adult liver, in that the signal assigned to PME is elevated compared with that for ATP, and that for PDE/ATP is reduced.¹² The chemical shift of the PME signal is 6.8 ± 0.1 ppm, suggesting that PE is a major component. This would be consistent with the findings from neonatal brain, in which an elevated PME level has been attributed to PE.

2.2 ¹H MRS

The ¹H spectrum is dominated by signals from water and lipid. While this spectrum can be used to evaluate the degree of fatty infiltration, for example, both resonances need to be suppressed in order to observe metabolite signals. There has been one early paper describing high-resolution *in vivo* hepatic MRS, tentatively assigning the minor peaks to carnitine, taurine, glutamate, and glutamine.¹³ Further *in vivo* studies have not been forthcoming, because of the problems of effective water and lipid suppression. However, the potential of ¹H MRS is illustrated by *in vitro* MRS studies of human tissue,¹ in which resonances from choline-containing groups, creatine, acetate, glutamine/glutamate, and glycogen have been assigned

to the main resonances in the aliphatic region. Less intense signals from threonine, succinate, alanine, citrate, glycine, aspartate, and taurine have also been observed. The aromatic region shows resonances from a number of metabolites including NTP, nucleotide diphosphate (NDP), AMP, NAD and NADH.

2.3 ¹³C MRS

The natural abundance of ¹³C is only 1.1%. Therefore the only endogenous metabolites detectable in the liver by natural abundance ¹³C MRS are storage compounds, such as triglycerides and glycogen, which can achieve high intracellular concentrations.

Fats are insoluble in water and are transported in the plasma as protein–lipid complexes (lipoproteins). The liver plays a major role in the metabolism of lipoproteins, synthesizing very low density proteins (VLDLs) and high density lipoproteins (HDLs). The liver and kidney are the major sites of HDL catabolism; low density lipoproteins (LDLs) are degraded by the liver after uptake by specific cell receptors. Triglycerides may be of dietary origin, but are also formed in the liver from circulating free fatty acids and glycerol and incorporated into VLDLs. There have been no studies to date interpreting the liver lipid profile with different diet or in disease. This reflects the fact that the concentrations of bulk triglycerides do not change sufficiently rapidly with time for short-term studies of fat metabolism to be carried out by this means.

On the other hand, glucose homeostasis and the maintenance of the blood sugar is an important function of the liver. In the fasting state, blood glucose is maintained either by glucose released from the breakdown of glycogen (glycogenolysis) or by newly synthesized glucose (gluconeogenesis). The relative contributions of these processes to glucose production have been difficult to quantify in humans, and therefore a noninvasive measurement at multiple time points of hepatic glycogen levels using ¹³C MRS is of considerable importance.

The chemical shift range of the ¹³C spectrum is 200 ppm, and the hepatic spectrum is dominated by resonances from saturated groups ($-\text{CH}_3$ and $-\text{CH}_2-$) from the fatty acyl chain at 15–35 ppm, unsaturated groups ($-\text{H}^*\text{C}=\text{CH}-$) from the fatty acyl chain at 128–131 ppm, and carbonyl groups ($-\text{C}^*\text{O}-$) from the fatty acyl chain at 172 ppm.¹⁴ The signal from C-1 of glycogen resonates at 100.5 ppm, away from other resonances, and is therefore the most easily detected peak from glycogen. Smaller resonances from ethanolamine, choline, glucose, and carbonyl groups in proteins and phospholipids are observed in high-resolution spectra of rat liver.¹⁴ While signals from triacylglycerides dominate the *in vivo* spectrum, often obliterating signals from other compounds resonating nearby, the majority of applications of hepatic ¹³C MRS have concentrated on the detection and quantitation of glycogen levels.^{15–19}

The relaxation times of glycogen are short; the T_1 is 240 ms and the T_2 is 30 ms,²⁰ so that rapid repetition times can be used. The sensitivity of measurement of the glycogen signal can be improved by proton decoupling²¹ or polarization transfer techniques.²² Signals from superficial lipids may need to be suppressed, for example by using shaped rf pulses, incorporation of an inversion pulse parallel to the coil axis at the sample surface,¹⁷ or by exploiting the characteristics of the surface transmitter–receiver coil.¹⁹

2.4 ^{19}F MRS

The body does not naturally contain ^{19}F and therefore there are no signals in the hepatic ^{19}F MRS spectrum of the normal liver. However, signals from ^{19}F -containing drugs or their metabolites can be detected, for example 5-fluorouracil (5FU), enabling information about the time course and metabolic pathways of the drugs to be obtained.²³

3 METHODOLOGY AND QUANTIFICATION

3.1 Field Strength

The majority of studies have been undertaken at field strengths of around 1.5 T. Boska et al. have formally compared the quality of hepatic ^{31}P MRS spectra at 1.5 T and 2.0 T.²⁴ The signal-to-noise ratio (S/N) of a localized hepatic ^{31}P MRS spectrum improved by $32 \pm 10\%$, which is comparable with the improvement by $33 \pm 13\%$ in the S/N of a spectrum from a loading phantom.

Hepatic spectra have been reported by two groups using 4 T systems, with the aim of illustrating the increased sensitivity and spectral dispersion obtained at higher field strengths.^{25,26} The hepatic ^{31}P MRS spectrum showed that resonances from PME, Pi, and PDE were well resolved, the two peaks from GPC and GPE in the PDE region could be distinguished, and resonances from nicotinamide adenine dinucleotide (NAD) and its phosphate (NADP) were seen as a shoulder on the $\alpha\text{NTP/NDP}$ peak.²⁶ The C-1 resonance from glycogen was detected at 4 T with an acceptable S/N in an acquisition time of 12–15²⁵ or 20 min.²⁶

3.2 Localization

In the majority of studies, localization to the liver has been achieved by a suitable choice of rf coils combined with localization techniques. By virtue of the position of the liver, a surface receiver coil has almost always been used. The transmitter coil has been the same or another surface coil (producing a nonuniform B_1 field)^{4,6} or a saddle-shaped transmit coil (producing a uniform B_1 field).⁷ Additional localization has generally been achieved using single volume methods, such as ISIS, or multivoxel techniques such as chemical shift imaging or rotating frame zeugmatography.²⁷ Choice of technique will depend to some extent on the clinical problem and on the timescale of spectral acquisition.

3.3 Quantification (see *Quantitation in In Vivo MRS*)

It is difficult to realize the full potential of the technique because a number of factors limit the accuracy with which absolute quantitation can be achieved in hepatic MRS. Nevertheless, the majority of centers have provided some measure of absolute quantitation in both hepatic ^{31}P and ^{13}C MRS.^{6,17,28,29} Factors to be borne in mind include the effect of respiratory motion, which causes ghosting of signals and

degrades spectral resolution³⁰ and is a problem common to all nuclei. The presence of paramagnetics broadens the water linewidth, for example, compared with the linewidth in the brain and muscle. However, reasonable linewidths can be achieved in the hepatic phosphorus spectrum, and linewidths of 11 Hz have been measured at 1.6 T for Pi.³¹ Another problem is the varying contribution of signals from overlying tissues, for example, subcutaneous lipid and posterior and anterior muscle. In ^{31}P MRS the contributions from muscle can be separated from the liver spectrum using the phosphocreatine signal as a marker for muscle. In both ^{13}C and ^1H MRS, contributions from subcutaneous lipid may be a serious problem, particularly if a surface coil is used, since these lipid signals are relatively intense and can mask the very much weaker metabolite signals.

Other factors need to be considered for hepatic ^{31}P MRS. Many of the signals are multicomponent, and the limited chemical shift dispersion of in vivo ^{31}P MRS spectra is a major cause of poor spectral resolution. Interpretation of a change in signal intensity to a specific metabolite or metabolites is often difficult without recourse to animal models or biopsy studies. The spectral resolution in the ^{31}P spectrum can be improved by ^{31}P – ^1H decoupling,⁵ since the three-bond coupling constant in, for example, PE, GPC, 2,3-DPG, and NAD, may become a dominant factor in determining the residual linewidth of these signals (see *Proton Decoupling During In Vivo Whole Body Phosphorus MRS*). Finally, the relaxation times T_1 and T_2 are difficult to characterize for each individual study because the T_1 values can be long and there is limited time available for a clinical examination. The overall T_1 of the multicomponent signals does vary in some pathologies,³² so it is not always possible to extrapolate from values obtained from healthy control subjects.

3.4 Relaxation Parameters in Hepatic ^{31}P MRS

A number of studies have specifically addressed the issue of T_1 measurement in healthy subjects. For example, Blackledge et al.³³ used an inversion–recovery depth-selection sequence based on rotating frame zeugmatography methods to measure T_1 values of the liver. They measured the T_1 of γATP to be 0.33 ± 0.05 s, that of PME as 0.74 ± 0.10 s, and that of Pi as 0.44 ± 0.06 s. The PDE peak appeared to exhibit heterogeneity in T_1 , with a fast component ($T_1 < 200$ ms) and a slowly recovering component ($T_1 > 1$ s). Due to off-resonance effects, Blackledge et al. could not quote values for other peaks.

Buchthal et al.³⁴ used progressive saturation techniques, in combination with a surface coil and one-dimensional phase encoding. A uniform 90° pulse was achieved by using an adiabatic half passage pulse that compensated for the spatially nonuniform rf field of the surface coil. The mean T_1 values from seven individuals were: Pi, 0.41 ± 0.1 s; PDE, 1.4 ± 0.13 s; and γATP , 0.68 ± 0.09 s.

Meyerhoff et al.⁶ used a fast inversion–recovery sequence, combined with ISIS, to measure T_1 relaxation values from four healthy volunteers. The results were: PME, 0.84 ± 0.26 s; Pi, 0.97 ± 0.25 s; PDE, 1.36 ± 0.37 s; γATP , 0.35 ± 0.06 s; αATP , 0.46 ± 0.09 s; and βATP , 0.35 ± 0.05 s.

Cox et al.³² estimated T_1 values, from a comparison of signal intensities at TR 0.5 and 5 s, to be: PME, up to 3 s; PDE, 3–6 s; Pi, 1 s; and βATP , 0.7 s.

4 MRS STUDIES IN PROTEIN, CARBOHYDRATE, AND LIPID METABOLISM IN THE NORMAL LIVER

The complex interrelationships between protein, carbohydrate and fat metabolism are illustrated in Figure 2. Different aspects of these pathways can be probed measuring spectral changes after a metabolic challenge.

The formation of glycogen has been followed under different conditions, for example after a long fast,¹⁷ an intravenous infusion of [1-¹³C]glucose under hyperglycemic and hyperinsulinemic clamp conditions¹⁹ and an oral intake of glucose in the form of bolus.^{18,19} Rothman et al.¹⁷ serially measured hepatic glycogen concentrations using ¹³C MRS at 3–12 h intervals during a 68 h fast. The liver volume was determined by MRI. Net hepatic glycogenolysis was calculated by multiplying the rate of glycogen breakdown by the liver volume. The net rate of gluconeogenesis was calculated by subtracting the rate of net hepatic glycogeneolysis from the rate of glucose production in the whole body measured with tritiated glucose. Even in the first 22 h of fast they found that gluconeogenesis accounted for a substantial fraction of total glucose production ($64 \pm 5\%$) and this increased to $82 \pm 5\%$ (22–46 h of fasting) and $96 \pm 1\%$ (46–64 h of fasting). These important results suggest that hepatic gluconeogenesis is always operating at an appreciable rate in humans.

Ishihara et al.¹⁸ measured glycogen and glucose resonances in one subject, after a bolus of glucose (100 g) following a 20 h fast, and also after administration of ¹³C enriched (99%) [1-¹³C]D-glucose (1 g) mixed with 75 g glucose.

Beckmann et al.¹⁹ followed the formation of glycogen in the liver of normal volunteers after an intravenous infusion of

[1-¹³C]glucose under hyperglycemic and hyperinsulinemic clamp conditions and an oral intake of glucose in the form of bolus. They found that changes in the glycogen signal correlated well with the time course of insulin and glucagon during the spectral measurement. They showed that liver glycogen formation in man can be followed using nonlabeled glucose or [1-¹³C]glucose with a low level of enrichment (16.6%). The use of nonlabeled glucose has the advantage that quantitation of net liver glycogen synthesis is simplified because label dilution through the various metabolic pathways of glucose is avoided. Measurements of glucose uptake, estimated from the increase in the glycogen signal, was consistent with findings from more complex and invasive studies of glucose uptake in the liver. The average liver glycogen concentration after a 12 h overnight fast in 18 volunteers without any dietary preparation was estimated to be 229 ± 34 mM.

Of the physiological precursors for hepatic gluconeogenesis, the amino acid L-alanine is of special importance since it is a key protein-derived gluconeogenic precursor. It is cleared rapidly by the liver and has a half-life of only 30 min in the plasma of healthy subjects. After an overnight fast the plasma concentration of glucose falls and glycolysis in the liver is inhibited while gluconeogenesis is stimulated. Infusion of L-alanine induces rapid and consistent changes in ³¹P MRS spectra (Figure 3).³⁵ A marked change with a clear dose–response relationship was observed for PME/ATP (maximal change +98%) and Pi/ATP (–33%), while smaller changes were demonstrated for PDE/ATP (+24%) which were independent of the alanine dose. Levels of ATP did not change, suggesting there was no change in phosphorylation status. In vitro MRS spectra obtained from animal models after alanine infusion showed marked increases in the gluconeogenic intermediates, 3-phosphoglycerate (PME region) and phosphoenolpyruvate (PDE region). Since the plasma glucose concentrations in humans were unaltered following the alanine infusion, MRS spectral changes have been interpreted as suggesting increased flux through the gluconeogenic pathway, possibly with glucagon rather than glucose as the endpoint. Therefore this metabolic stress test constitutes a useful tool for use in studies of gluconeogenesis.

Conventional liver function tests measure plasma clearance of the compounds metabolized by the liver, but these can be influenced by extrahepatic factors such as renal excretion. Therefore a direct measure of liver function would be of value. One example studied in detail has been a measure of hepatic sugar metabolism following a rapid intravenous bolus injection of fructose,^{4,36,37} and the dose–response curves have been established.³⁶ Fructose is a major source of carbohydrate in the Western diet and is metabolized mainly in the liver. It is rapidly metabolized to fructose 1-phosphate by fructokinase in the liver, causing a rapid decrease in ATP and Pi. Thus, following intravenous infusion of fructose (bolus injection of 200–250 mg kg^{–1}) findings using hepatic ³¹P MRS showed there was an approximately threefold increase in PME, predominantly fructose 1-phosphate, by 10 min and a return to basal values by 20–30 min. The hepatic concentration of Pi decreased by more than 80% immediately after fructose infusion, while the plasma Pi concentration dropped by only 20%. Pi levels rebounded and hepatic Pi concentration was increased to about three times the preinfusion values by 15 min. Thereafter, hepatic Pi levels gradually decreased, while plasma Pi

Figure 3 Representative ^{31}P NMR spectra of normal human liver before and after a bolus infusion of L-alanine $2.80 \text{ mmol kg}^{-1}$ body weight. ^{31}P NMR data were acquired using a two-dimensional pulse sequence with a repetition time of 1 s and a pulse angle of 45° (256 signal averages). Spectra shown are plotted on the same absolute scale (referenced to the highest ATP peak of the whole set of spectra), so that absolute peak areas of all spectra are comparable. Two baseline spectra were obtained (a and b). Time after start of L-alanine infusion (i.e. midtime-point of data collection referenced to start of infusion) for spectra (c–h): (c) 8, (d) 13, (e) 26, (f) 39, (g) 67, and (h) 103 min. (Reproduced by permission of the Biochemical Society and Portland Press from P. C. Dagnelie, D. K. Menon, I. J. Cox, J. D. Bell, J. Sargentoni, G. A. Coutts, J. Urenjak, and R. A. Iles, *Clin. Sci.*, 1992, **83**, 183)

increased. The changes in Pi were several times greater in liver cells than in blood plasma, suggesting that large concentration gradients had been generated across the liver cell membrane. Hepatic ATP levels showed a transient decrease by 60% after infusion of fructose, but after 60 min the ATP pool was still reduced by about 40%, and this was attributed to the breakdown of ATP to inosine monophosphate and, ultimately, to uric acid. These changes in PME, Pi, and ATP showed a linear dose dependence.³⁶

5 DIFFUSE LIVER DISEASE

5.1 Diabetes

Alterations in glucose–glycogen metabolism are important consequences for a number of diseases. For example, type II diabetes mellitus is characterized by fasting hyperglycemia and an excessive, prolonged rise in the plasma glucose concentration after glucose or meal ingestion. Magnusson et al.³⁸ measured glycogenolysis and gluconeogenesis in seven type II diabetic subjects and five control subjects during 23 h of fast-

Figure 4 Typical ^{13}C NMR spectrum of the C-1 position of liver glycogen from one control subject (left panel) and one type II diabetic patient (right panel) 4 h after the liquid meal. (Reproduced by permission of The American Society for Clinical Investigation, Inc., from I. Magnusson, D. L. Rothman, L. D. Katz, R. G. Shulman, and G. I. Shulman, *J. Clin. Invest.*, 1992, **90**, 1323)

ing. They found that increased gluconeogenesis was responsible for the increased whole body glucose production in type II diabetes mellitus after an overnight fast. In detail, 4 h after a meal liver glycogen concentration was lower in diabetics than in controls, 131 ± 20 versus $282 \pm 60 \text{ mmol L}^{-1}$ liver ($p < 0.05$) (Figure 4). Net hepatic glycogenolysis was decreased in the diabetics, 1.3 ± 0.2 versus $2.8 \pm 0.7 \mu\text{mol per (kg body wt} \times \text{min)}$, $p < 0.05$. Whole body glucose production was increased in the diabetics, 11.1 ± 0.6 versus $8.9 \pm 0.5 \mu\text{mol per (kg body wt} \times \text{min)}$, $p < 0.05$. Gluconeogenesis was consequently increased in the diabetics, 9.8 ± 0.7 versus $6.1 \pm 0.5 \mu\text{mol per (kg body wt} \times \text{min)}$, $p < 0.01$, and accounted for $88 \pm 2\%$ of total glucose production compared with $70 \pm 6\%$ in controls, $p < 0.05$.

5.2 Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) is a rare autosomal recessive disorder. The effect of fructose on liver metabolism in patients with HFI and in heterozygotes for HFI has been studied by hepatic ^{31}P MRS.³⁹ In five patients with HFI small amounts of fructose (1.5 g) were followed by an increase in sugar phosphates and a decrease in Pi, and it was suggested that hepatic ^{31}P MRS could be used to diagnose fructose intolerance and to monitor patients' compliance with a fructose-restricted diet. In eight heterozygotes, ingestion of much larger amounts of fructose (50 g) led to an accumulation of sugar phosphates, a reduction of Pi, and a larger increase in plasma urate compared with control subjects. The effects were most pronounced in heterozygotes with gout, and it was suggested that heterozygosity for HFI may predispose to hyperuricemia.

5.3 Familial Gout

The hyperuricemia responsible for the development of gouty arthritis results from a wide range of environmental factors and, less commonly, from inborn errors of metabolism. As a continuation from the studies on homozygous and heterozygous patients with HFI, 11 volunteers with familial gout were examined with hepatic ^{31}P MRS following a 50 g load of oral fructose.⁴⁰ Spectral changes in response to the fructose load similar in magnitude to those observed in earlier studies of

obligate heterozygotes for HFI were found in 2 of the 11 patients with familial gout. In one family the index patient's three brothers and his mother all showed the fructose-induced abnormality of metabolism, in agreement with the maternal inheritance of the gout in this family group. The test dose of fructose used produced a significantly larger increment in the concentration of serum urate in the patients showing changes on hepatic ^{31}P MRS. The biochemical basis for the fructose-induced increase in purine metabolism was discussed, and it was suggested that a lower activity of aldolase B prevailed in the two patients with hereditary gout who showed fructose-induced abnormality of metabolism. It was suggested that in these two subjects the causal role for generating gout is the aberrant fructose metabolism, and indeed that a restriction of fructose ingestion is a possible approach to the clinical management of patients with this disorder.

5.4 Cirrhosis

The clinical spectrum of cirrhosis varies widely, and adequate characterization of the functional state is therefore essential for making management decisions in these patients. At present, characterization usually depends on the assessment of indirect clinical and laboratory measurements of hepatic function. These parameters provide some measure of the functional grade of cirrhosis, but are subject to extrahepatic influences that may reduce their value as markers of liver function. Quantitative estimates of liver function may also be obtained from various clearance studies, but individual tests may not provide a good picture of overall liver function.

Several groups of workers have used hepatic ^{31}P MRS to study subjects with alcoholic cirrhosis and chronic liver disease of other etiologies,^{28,29,41-45} and two studies have addressed hepatic ^{31}P MRS in the context of varying functional severity of liver disease.^{43,45} The results from different centers are not consistent, reflecting differences in the acquisition parameters (and, therefore, the degree of quantitation) and also differences in clinical state of the patients.

Patients with alcoholic liver disease were studied using image-guided hepatic ^{31}P MRS methods, to yield an estimate of absolute molar concentrations of phosphorus metabolites in a 64–120 cm³ volume within the liver.⁴¹ The patient group included nine patients with alcoholic cirrhosis of varying severity. The pH value was more acidotic in the cirrhotic patient group (7.26 ± 0.2) compared with controls (7.44 ± 0.2) ($p = 0.04$). The chemical shifts of the other peaks were not significantly different between the cirrhotic and control group. The metabolite ratios were similar in the control and cirrhotic group. However, absolute concentrations of metabolites were decreased by 13–50%. Except for the decrease in PME of 13%, all the decreases from values obtained in normal liver were significant ($p < 0.05$). There was no significant difference between the absolute values for cirrhotics and hepatitics.

In a study of patients with alcohol liver disease, including five patients with cirrhosis, Angus et al.⁴² found no change in any of the metabolite ratios in the patients with cirrhosis. There was no change in Pi/ATP, suggesting no evidence of impaired cellular energetics. The hepatic pH was also similar in patients with cirrhosis and in controls. This patient group had previously been found to have established cirrhosis, and had been abstinent from alcohol for at least 6 months.

Absolute concentrations were measured using one-dimensional chemical shift imaging (CSI) techniques in five healthy volunteers and five patients with alcoholic cirrhosis.²⁹ Absolute metabolite levels were calculated with reference to an external standard. Metabolite ratios were not altered in cirrhosis compared with controls, although absolute concentrations of all hepatic metabolites tended to be lower. However, only the reduction in βATP , of 31%, was significant. Histological evidence suggested that the reduction in ATP levels reflected fewer functioning liver cells per volume of liver, since functional cells had been destroyed and replaced by fibrosis. The amount of ATP per liver parenchymal cell was thought to be unchanged. The authors suggested that metabolite ratios were of limited diagnostic value in the assessment of alcoholic cirrhosis, if they were unsupported by quantitative analysis.

Fourteen patients with liver cirrhosis of differing severity were examined using one-dimensional CSI methods.⁴³ Patients were divided into two groups according to the severity of their liver disease using Child's classification and the aminopyrine breath (AB) test. The PME/total phosphorus ratio was significantly higher in patients with mild and severe cirrhosis. There was no change in the PME T_1 value in cirrhotics. There was a significant negative linear correlation of PME with percentage dose of $^{14}\text{CO}_2$ excreted over 2 h in the AB test. The pH values were significantly elevated in mild cirrhosis (pH 7.45), but not in severe cirrhosis (pH 7.36), compared with controls (pH 7.29). This was the first paper highlighting the clinical potential of hepatic ^{31}P MRS as a noninvasive means of assessing the severity of liver cirrhosis.

In a study of a group of 86 patients with histologically proven cirrhosis of varying etiology and functional grade (Menon et al.⁴⁵), patients with liver disease showed a significantly higher median PME/ATP ($p < 0.0001$), PME/PDE ($p < 0.0001$), PME signal height ratio (SHR) ($p < 0.0001$), and Pi SHR ($p < 0.02$), and a lower median PDE/ATP ($p < 0.001$) and PDE SHR ($p < 0.001$) (the SHR was obtained by dividing the peak height at TR 5 s by that at TR 0.5 s to yield a T_1 -related SHR). The magnitude of these changes significantly and progressively increased with worsening functional state (Figure 5).

Figure 5 Hepatic ^{31}P MR spectra collected using a two-dimensional CSI sequence with TR T_p -5 s, pulse angle 45° from a healthy volunteer, and patients with Child's A, B and C functional grades of alcoholic cirrhosis

Etiological differences were noted in patients with compensated cirrhosis. Spectra from patient with cirrhosis secondary to viral hepatitis showed a significantly higher PME/ATP, Pi/ATP, and PME/PDE, and those with cirrhosis secondary to primary sclerosing cholangitis showed a significantly lower Pi/ATP than did other etiological groups.⁴⁵ However, spectral appearances did not vary with etiology of cirrhosis in decompensated patients. In vitro ³¹P MRS of perchloric extracts of biopsy samples of liver tissue obtained from 10 patients with cirrhosis at transplant hepatectomy showed increases in levels of PE and PC, and a reduction in levels of GPE and GPC. These changes suggest regenerative activity in cirrhotic livers. The reduction in soluble PDE in the aqueous extracts did not quantitatively account for the reduced PDE resonance seen in vivo, and the changes seen in vivo may therefore be partly due to reduction in contributions from hepatic endoplasmic reticulum, resulting from replacement of hepatocytes by fibrous tissue.

In order to determine the feasibility and utility of dynamic hepatic ³¹P MRS, Dufour et al. studied six healthy subjects and nine patients with nonalcoholic cirrhosis after an intravenous infusion of a fructose load (250 mg kg⁻¹).⁴⁴ The basal spectra between the healthy and cirrhotic subjects had comparable metabolite areas, except that the contribution of PDE was significantly smaller in cirrhotic patients than in healthy subjects (33 ± 5% versus 38 ± 5%; *p* < 0.05). In both groups, the relative PME peak increased and then returned to basal values, Pi decreased then rapidly increased and overshot basal values and slowly returned to basal values, and βATP decreased and slowly returned to basal values. However, in the cirrhotic group the magnitude of these changes were reduced; PME increased to 9 ± 5% versus 20 ± 8% in controls, Pi decreased by 5 ± 4% versus 11 ± 3% of total area (*p* < 0.005). These measurements correlated with the severity of the impairment of liver function measured by galactose-elimination capacity.

5.5 Alcoholic Hepatitis

As with studies on alcoholic cirrhosis the hepatic MRS findings varied according to the MRS technique used, the degree of quantitation achieved and the clinical state of the patient. Meyerhoff et al.⁴¹ found that in 10 patients absolute concentrations of metabolites were decreased by 25–44%, but there was no change in metabolite ratios. Also, intracellular pH was more alkaline in the patient group compared with controls.

Angus et al.⁴² measured the metabolite ratios to be abnormal in 16 patients with hepatitis, none of whom had consumed alcohol within the previous 72 h. PME/Pi and PME/ATP were elevated, and the PME level showed a significant positive correlation with the severity of alcoholic hepatitis, assessed by histology. Pi/ATP and pH were similar to control values. These data were similar to findings from four other patients previously studied by the same group.²⁸

5.6 Viral Hepatitis

A number of patients with viral hepatitis have been studied, generally as a subgroup of a study of a heterogeneous patient group. Elevated PME/ATP has been reported in five patients with acute viral hepatitis,²⁸ three patients with viral hepatitis B,⁴¹ and one patient with non-A non-B hepatitis.⁷ Oberhaensli

et al. found that the high phosphomonoesters returned to normal as liver function became normal, suggesting they were probably associated with liver regeneration 1–2 weeks after the onset of jaundice when the investigations were performed.²⁸

5.7 Chronic Hepatitis

Serial changes in phosphorus metabolites were monitored after fructose infusion in five patients with chronic hepatitis.⁴⁶ Following 0.5 g kg⁻¹ fructose the increase in PME at 15–20 min (151 ± 49% of the preadministration value) was significantly less than in healthy volunteers (*p* < 0.05). Also, the rebound of Pi at 35–40 min (126 ± 42%) was significantly less than that in healthy volunteers (*p* < 0.05). These findings were interpreted as suggesting that reduced fructose utilization is caused by impaired fructose transport into liver cells, thus indicating that this is a promising method in the functional evaluation of certain diffuse liver diseases.

5.8 Glycogen Storage Disease

Over 10 forms of glycogen storage disease resulting from inherited enzyme defects have been characterized. The different diseases are characterized by a storage of glycogen in abnormal quantities and/or synthesis of glycogen with an abnormal structure.

Beckmann et al.⁴⁷ obtained hepatic ¹³C MRS spectra from one patient with type IIIA glycogen storage disease, which is characterized by an increased glycogen concentration of abnormal structure in liver and muscle, due to inactivation of the amylo-1,6-glucosidase debrancher enzyme. They found glycogen levels, measured from the C-1 resonance, to be increased by a factor of 2–3 compared with well-trained athletic normals.

A hepatic ³¹P MRS study of two patients with glucose 6-phosphatase deficiency (glycogen storage disease type 1A) showed that, after an overnight fast, PME was increased and Pi was low-normal (Pi/PME was markedly reduced).⁴⁸ The increase in PME was attributed to accumulation of sugar phosphates (mainly glycolytic intermediates), on the basis of chemical shift measurements. After 1 g kg⁻¹ oral glucose, hepatic sugar phosphates decreased by 40–64% and reached normal levels, whereas Pi increased by 40–130%. Liver Pi levels remained elevated in both patients 30 min after ingestion of glucose. Liver PME and Pi levels did not change in four control subjects after a glucose load. These high levels of PME were interpreted as suggesting that the activity of residual glucose 6-phosphatase may be enhanced, thus increasing hepatic glucose production and reducing the degree of hypoglycemia during fasting. The finding of large fluctuation in hepatic Pi levels may be directly related to the increase in uric acid production typically seen in these patients.

5.9 Galactose Intolerance

Galactosemia is an autosomal recessive disorder caused by a deficiency of the enzyme UDPglucose:α-D-galactose-1-phosphate uridylyltransferase (EC 1.7.7.12). Liver damage is thought to be caused by accumulation of metabolites of galactose, although the exact mechanism is unclear. In a study of two galactosemic patients,⁴⁹ an oral load of 20 mg kg⁻¹ produced significant changes in the hepatic ³¹P MRS spectrum of one of

the patients. The peak at 5.2 ppm increased on two occasions to about twice its original size 60 min after galactose administration. In vitro animal studies showed this increase was largely due to galactose 1-phosphate.

5.10 Miscellaneous

Hypothyroidism is known to affect nearly every organ and organ system in the body. However, in seven patients with severe hypothyroidism there were no differences in the hepatic ^{31}P MRS spectra compared with controls, either before or after treatment with thyroid hormone substitution therapy.⁵⁰

In a study of seven patients with iron overload²⁸ (ferritin levels 600 to >3000 mg mL⁻¹), the hepatic ^{31}P MRS resonances were all broadened, resulting in part from susceptibility effects of Fe³⁺, which is stored as ferritin and hemosiderin in liver lysosomes. The line broadening correlated with the degree of iron overload.

6 FOCAL LIVER DISEASE

The majority of applications of NMR to focal liver disease have involved tumors, and these have recently been reviewed by Negendank.⁵¹ Ideally, the tumor spectrum should be compared with the normal spectrum of cells from which the neoplasm arises, which is possible for primary liver cancers, but not for secondary liver tumors. A further problem arises because the normal liver spectrum has prominent PME and PDE signals, and as these are signals that are abnormal in tumors it can be difficult to define the tumor spectrum.

The ^{31}P MRS characteristics of hepatic tumors in adults are summarized in Table 1 and Figure 6. A number of technical points must be noted: in the majority of studies peak intensities were reported as relative ratios of areas, and molar quantitation was only attempted in two studies; most spectra were reported to be contaminated with signals from background tissue, but few authors provided estimates of the extent of contamination; and data were partially saturated, so that the effect of any

difference in T_1 was not taken into account when comparing cancer and normal hepatic spectra. Despite these comments, a number of points can be made. The most obvious and most consistent abnormality is an elevation of PME. The change in PDE is less consistent, with some groups reporting an elevation and others reporting a reduction. Changes in the Pi signal showed no obvious pattern. The pH in tumors was either similar or slightly higher than that of normal tissue. Furthermore there were no obvious differences between different types of tumor, either between primary and secondary tumors or between secondary tumors from different sites. It is interesting that there appears to be no obvious compromise of energy metabolism, and effects of ischemia or hypoxia do not dominate the tumor spectrum.

Thus, in distinguishing neoplasms from normal tissue, only PME can be considered a diagnostic discriminant. Since proton decoupling during acquisition of the ^{31}P MRS data has not been performed in human tumor studies, there is no direct information on individual components in vivo. However, high-resolution MRS of perchloric acid extracts of tissue obtained at the time of surgery show that phosphoethanolamine and phosphocholine were elevated in four hepatocellular carcinomas and four secondary tumors.^{1,56}

It is hoped that MRS will provide a marker of treatment response, particularly in the early stages of therapy. For example, hepatic embolization combined with intraarterial administration of cytostatic changes (chemoembolization) may be used to treat primary and metastatic cancers to the liver. As an acute response to chemoembolization in three patients, ATP, PME, and/or PDE concentrations diminished, whereas Pi concentrations increased or stayed relatively constant.⁵² Long-term follow-up after chemoembolization showed elevated PME/ATP and increased ATP concentrations in the absence of changes by conventional imaging techniques.⁵² In another study of 10 patients with liver metastases from colorectal carcinoma and two patients with hepatocellular carcinoma a marked increase in Pi and a decrease in ATP were observed during the first few hours after local chemotherapy of chemoembolization and later, PME increased and PDE decreased.⁵⁵ In a study of two

Table 1 ^{31}P MRS Spectral Parameters for Patients with Hepatic Malignancy ($n \geq 2$)

Diagnosis	<i>n</i>	MRS findings ^a
<i>Primary malignancy</i>		
Hepatocellular carcinoma ⁵²	2	PME/ATP ↑
Hepatocellular carcinoma ⁵³	7	PME/ATP ↑, if tumor occupied more than 50% of VOI
Hepatocellular carcinoma ⁵⁴	3	PME/Pi ↑, PME/ATP ↑
Hepatocellular carcinoma ⁵⁵	2	PME ↑
Various ⁵⁶	3	PME/PDE ↑
<i>Secondary malignancy</i>		
Lymphoma ⁵⁷	22	PME/ATP ↑, PME/Pi ↑
Adenocarcinoma ⁵⁶	11	PME/PDE ↑
Carcinoid ⁵⁶	14	PME/PDE ↑
Various ⁵²	3	PME/ATP ↑, ATP ↓, Pi ↓
Various ^{28,59}	3	PME ↑
Breast carcinoma ⁵⁴	2	PME/ATP ↑, PME/Pi ↑, PDE/Pi ↑, pH ↑
Various ⁵⁸	19	PME/ATP ↑, PDE/ATP ↑, Pi/ATP ↑
Colorectal carcinoma ⁵⁵	10	PME ↑
Various ⁵³	30	PME/ATP ↑, if tumor occupied more than 50% of VOI

Figure 6 Representative ^{31}P hepatic MRS spectra obtained from a healthy adult volunteer and patients with hepatic malignancies of varying histology using CSI techniques, $TR=1$ s, pulse angle 45° . (a) Spectrum from a healthy 22-year-old female acquired using two-dimensional CSI; nominal planar resolution, 30 mm; total number of data collections, 256. (b) Spectrum from a 61-year-old man with squamous cell carcinoma obtained from a voxel containing tumor acquired using four-dimensional CSI; nominal resolution, 30 mm $\times$ 30 mm; total number of data collections 2048. (c) Spectrum from a 59-year-old man with carcinoid liver metastases obtained from a voxel containing tumor acquired using four-dimensional CSI; nominal resolution, 20 mm $\times$ 20 mm $\times$ 20 mm; total number of data collections 2048. (d) Spectrum from a 56-year-old man with carcinoid liver metastases obtained from a voxel containing tumor acquired using four-dimensional CSI; nominal resolution, 30 mm $\times$ 30 mm $\times$ 30 mm; total number of data collections 2048. (e) Spectrum from a 79-year-old man with carcinoid liver metastases obtained from a voxel containing tumor acquired using four-dimensional CSI; nominal resolution, 30 mm $\times$ 30 mm $\times$ 30 mm; total number of data collections 2048. (f) Spectrum from a 53-year-old man with hepatocellular carcinoma obtained from a voxel containing tumor acquired using four-dimensional CSI; nominal resolution, 30 mm $\times$ 30 mm $\times$ 30 mm; total number of data collections 2048. (Reproduced by permission of Heydon & Son from I. J. Cox, J. D. Bell, C. J. Peden, R. A. Iles, C. S. Foster, P. Watanapa, and R. C. N. Williamson, *NMR Biomed.*, 1992, **5**, 114)

patients with carcinoid syndrome, successful arterial embolization was accompanied by a decrease in PME/PDE and an increase in Pi/ATP, whereas in a patient in whom the tumor blood supply was not effectively interrupted there was little change in metabolite ratios.⁷

In a study of 22 patients with lymphoma, 11 were re-examined after chemotherapy treatment.⁵⁷ Before treatment, PME/ATP and PME/Pi were elevated and approximately related to clinical stage, although there were some notable discrepancies.

Liver phosphomonoester levels decreased following chemotherapy in all but one of the patients who had abnormally high ratios in their initial spectra; this decrease was seen as early as 1 day and as late as 2 weeks after commencing treatment. In patients with initially normal PME levels, treatment did not produce a fall in PMEs. These findings suggest that detection of falling PME levels indicates that the drugs are reaching the target cells and affecting tumor cell metabolism, which may be of considerable clinical importance.

A study of two children with neuroblastoma⁶⁰ examined on a number of occasions from the ages of 1–9 months, showed the hepatic ^{31}P MRS spectrum from the region of pathology to be abnormal with elevated PME levels in the initial spectroscopic examinations. Further treatment showed a reduction in PME levels, and the spectra finally became similar to the normal subject (aged 3 months).

A small number of other focal liver lesions have been studied.^{54,58} The metabolite ratios from two patients with cavernous hemangiomas were apparently normal, although the S/N was reduced.⁵⁴ The in vitro high-resolution MRS spectra from a multiloculated cyst showed elevated PME and reduced PDE, and this was similar to data from extracts of tumor tissue.¹

7 DRUGS AND THE LIVER

The liver is the major site of drug metabolism. Lipid-soluble drugs are converted to more water-soluble forms by a group of hepatic mixed-function enzymes, including cytochrome P450. These processes facilitate excretion of the drugs in urine or bile. Drug metabolism firstly involves oxidation, reduction, or demethylation of the drug, followed by conjugation of the derivatives produced with glucuridine, sulfate, or glutathione. These conjugates are excreted in the urine and bile as they cannot be reabsorbed by renal tubular or bile ductular cells. A number of factors affect drug metabolism, including the microsomal enzyme system (which will influence the speed of metabolism), the route of administration, the liver blood flow, and competitive inhibition.

The majority of studies involving alcohol abuse have reported the spectral characteristics of resultant liver damage, rather than the effects of alcohol per se.^{28,29,41–45} However, it may be important to distinguish between the two effects, particularly as the metabolic consequences of an alcohol load may persist for a few hours to a few weeks and may depend on the degree of liver injury.

In a study of three healthy volunteers, acute alcohol ingestion (0.5–1.0 g kg^{-1} alcohol) was associated with a transient but significant elevation in PME/ATP.⁶¹ In 14 patients with minimal liver injury, active drinking was associated with elevation in mean PME/ATP ($p = 0.12$) and in mean PDE/ATP ($p < 0.0001$); abstinence from alcohol was associated with a prompt (3–7 day) reduction in PME/ATP and with a reduction in PDE/ATP over a longer timescale (3–28 days). In eight patients with alcoholic cirrhosis, active drinking was associated with elevation in mean PME/ATP ($p < 0.05$) and mean PDE/ATP ($p = 0.4$); abstinence from alcohol had no effect on the mean PME/ATP, although the mean PDE/ATP fell to within or below the reference range. The reversible elevation in PME/ATP in healthy volunteers given an alcohol load and in chronic

Figure 7 Serial ^{19}F spectra acquired with a surface coil over the liver of a patient (66 year old male) in a 1.5 T MRI system, operating at 59.8 MHz for ^{19}F . Each spectrum is the result of 128 FIDs using a 250 μs , 90° pulse with 512 complex points collected over a period of 8.5 min. Actual spectral width was 29 to -54 ppm. A shifted sine-bell squared apodization was used for S/N enhancement. (Reproduced by permission of Pergamon Journals Ltd. from W. Wolf, M. J. Albright, M. S. Silver, H. Weber, U. Reichardt, and R. Sauer, *Magn. Reson. Imag.*, 1987, **5**, 165)

alcohol abusers while actively drinking was interpreted as reflecting changes in hepatic redox potential as a result of obligatory alcohol metabolism. The irreversible elevation in PME/ATP, observed in patients with cirrhosis, probably reflects changes associated with hepatocyte regeneration. The reversible elevation in PDE/ATP observed in chronic alcohol abusers while actively drinking most likely reflects induction of hepatocyte endoplasmic reticulum.

Self-poisoning with acetaminophen accounts for many emergency hospital admissions. Overdoses cause cell damage through increased oxidation of the drug as the conjugation pathways are saturated. Early prediction of outcome in patients with acetaminophen overdose is difficult; for example, aspartate aminotransferase levels peak late after the ingestion of the drug and correlate poorly with prognosis. While the prothrombin time gives some indication of synthetic ability, methods for directly assessing cell viability are sought. Dixon and colleagues⁶² studied 18 patients with acetaminophen poisoning and found that the concentrations of all metabolites fell in parallel with a decrease in the synthetic ability of the liver. ATP and PDE fell to about 20% of their normal concentrations in severely affected patients. The reduction in PDE was interpreted as a reduction in endoplasmic reticulum.

The direct observation of 5FU and its metabolites in the human liver was first reported in 1987.⁶³ Signals from 5FU and one of its catabolites, α -fluoro- β -alanine (FBAL), were observed in the human liver in patients undergoing cancer chemotherapy (Figure 7). The pharmacokinetics of 5FU in the tumors of 11 patients with carcinoma at various sites were studied, including three patients with tumor located in the liver.⁶⁴ A long liver tumor pool of 5FU was observed in six of 11 tumors, including one of three patients with carcinoma in the liver. The half-life of this 'trapped' pool was 0.33–1.3 h, considerably longer than the half-life of 5FU in blood (5–15 min). Neither the anabolites or catabolites of 5FU were detected by

^{19}F MRS. Patient response to chemotherapy appeared to correlate with the extent of trapping of free 5FU in tumors.

Semmler et al.⁶⁵ reported hepatic ^{19}F MRS data from eight patients with liver tumors, receiving intra-arterial 5FU. Contributions from liver and tumor could not be distinguished in the spectrum. The time constants for the kinetics of 5FU ranged from 8 to 75 min, whereas the time constants for FBAL were either approximately 15 or 50 min. A broad peak comprising nucleoside and nucleotide anabolites was detected in one patient.

More recently, Findlay et al.⁶⁶ studied hepatic ^{19}F MRS in 26 colorectal cancer patients treated with a continuous low dose intravenous infusion of 5FU, until the point of refractory disease, at which time interferon- α was added with the objective of modulating 5FU activity. In patients observed by MRS during the first 8 weeks of 5FU treatment, those with a visible 5FU signal were likely to respond to treatment ($p = 0.017$). At the time of interferon- α addition, MRS showed that seven patients developed new or increased 5FU signals, and four patients showed a signal from the active metabolites of 5FU. The patients who exhibited a new or increased 5FU signal were more likely to show further response to interferon- α ($p = 0.007$).

The in vivo pharmacokinetics of a model drug, fleroxacin, was studied in healthy human subjects.⁶⁷ After oral administration a signal was detected in the hepatic ^{19}F MRS spectrum, and also muscle, and monitored over a period of 24 h. Pharmacokinetic data for the liver were obtained, combining MRS results with high-performance liquid chromatography (HPLC) analysis of plasma: $t_{\text{max}} = 1.4$ h; $C_{\text{max}} = 53 \mu\text{mol L}^{-1}$; $t_{1/2} = 4.4$ h (fast phase) and 10.8 h (slow phase).

8 FUTURE APPLICATIONS

Hepatic MRS can provide a direct measure of hepatic function, for example from the baseline spectrum or following a metabolic challenge. Since the indirect clinical and laboratory measures of hepatic function may be subject to extrahepatic influences, direct noninvasive measurement is of importance. A range of studies have been made, as described above, and these can be extended, for example, specifically to study gluconeogenesis in diabetics and tumor-bearing patients using ^{13}C or ^{31}P MRS combined with an alanine stress test. In addition, the interpretation that metabolite changes in end-stage liver disease can provide an index of hepatocyte regeneration, rather than reflecting production of fibrous tissue or inflammatory cell activity, suggests that hepatic ^{31}P MRS may provide a specific marker which could be used to guide management decisions and as a prognostic assessment in patients with liver disease. Further studies correlating functional grades and etiology to absolute metabolite levels are appropriate.

The clinical management of a range of pathologies relies on the interpretation of histological results from liver biopsy. Since liver biopsy has a defined risk, a noninvasive technique of providing the same information would be of value, particularly when serial liver biopsies are required, for example in patients undergoing liver transplantation. In such patients hepatic MRS may be used to provide a guide to optimal timing of transplantation, to indicate good or poor liver metabolic status for noninvasive assessment of donor livers prior to transplan-

tation⁶⁸ and also to provide a useful early marker of rejection after transplantation.

For patients with hepatic malignancy, ³¹P MRS may provide an early marker of response to treatment, and ¹⁹F MRS can be used to measure the pharmacokinetics of specific anticancer drugs and their metabolites. Other areas of study include the metabolism of the liver in patients with tumor at distant sites. Hepatic MRS may provide insights into the mechanisms responsible for cachexia.

Many of the clinical and biochemical applications of hepatic MRS to date have relied on the interpretation of changes in metabolite ratios, rather than absolute metabolite concentrations. However, in a number of pathologies, metabolite ratios alone do not adequately reflect the underlying metabolic changes, particularly if there is an alteration in ATP levels. Recourse to absolute metabolite concentrations is therefore required. This may be difficult to achieve within the confines of a clinical examination because the low S/N of hepatic spectra means it is time consuming to measure the NMR characteristics of individual resonances. Improvements in sensitivity and/or spectral resolution may be achieved using proton decoupling techniques, higher field strengths, and more efficient rf coil arrangements. However, detailed interpretation of clinical data will continue to rely on results from animal models. A wide range of metabolite resonances can be detected using ¹H MRS,¹ and, if the technical problems in acquiring hepatic ¹H MRS spectra can be overcome, hepatic ¹H MRS will provide additional and new information.

In conclusion, hepatic MRS can provide a noninvasive measure of hepatic function, which has a range of clinical and biochemical applications in diagnosis, prognosis, and assessment of treatment efficacy in liver disease.

Kidney, Prostate, Testicle, and Uterus of Subjects Studied by MRS

Michael W. Weiner

University of California, San Francisco, CA, USA

1 KIDNEY

1.1 Proton MRS of Kidney

Shah et al.¹ reported a technique for using the stimulated echo amplitude mode (STEAM) sequence for ¹H MRS of the human kidney. The results demonstrated the presence of trimethylamines (TMAs). A prominent peak observed at 5.8 ppm was from urea. Avison et al.² used volume localized ¹H MRS to detect and measure changes in medullary trimethylamines in the human kidney (Figure 1). Proton magnetic resonance spectra were obtained from the human renal medulla using a stimulated echo localization sequence.

In addition to residual water and lipid, TMAs were identified at 3.25 ppm. In normal volunteers, overnight dehydration led to a significant increase of urine osmolality, and an increase in medullary TMAs (Figure 2). Water loading caused a water

Figure 1 Water suppressed, volume localized ¹H spectrum from kidney. Water suppression consisted of a Silver-Hoult phase swept adiabatic fast passage pulse for selective water inversion followed by an inversion-recovery time of 0.8 second to allow the water Z magnetization to null. This sequence was delivered at the start of the volume localized stimulated echo sequence. $TE = 68$ ms, $TM = 44$ ms, $TR = 3$ s. Number of scans = 128. Filtering was 5 Hz of exponential line broadening. The resonances are water (4.75 ppm), lipids (0.9–1.4 ppm), and TMA (3.25 ppm)—which is shown expanded ($\times 8$) above the main spectrum. (Reproduced by permission of the National Academy of Sciences from Avison et al.²)

Figure 2 Time-course of changes in medullary TMA levels and U_{osm} in the four volunteers studied. TMA levels are expressed as the TMA area (%) at the point of maximal dehydration (i.e. $t = 0$). Error bars are $\pm$ SEM. * $p < 0.05$ versus $t = 0$ value for the TMA time-course. ** $p < 0.05$ versus $t = -15$ for the U_{osm} time-course. E, euvoletic; D, dehydration; W, water load. (Reproduced by permission of the National Academy of Sciences from Avison et al.²)

diuresis and a significant reduction in medullary TMAs within 4 hours. These results are consistent with the view that TMAs may play an osmoregulatory role in the medulla of the normal human kidney.

1.2 Phosphorus-31 MRS of Kidney

Jue et al.³ demonstrated that ³¹P MRS signals can be obtained from the normal human kidney. Matson et al.⁴ also demonstrated the feasibility of obtaining ³¹P magnetic resonance spectra from human kidneys using the image selected in vivo spectroscopy (ISIS) localization technique. Boska et al.⁵ obtained spatially localized ³¹P magnetic resonance spectra from healthy normal human kidneys and from well functioning renal allografts (Figure 3). Little or no phosphocreatine (PCr) in all spectra verified the absence of muscle contamination and was consistent with proper volume localization. The PME/ATP ratio (PME, phosphomonoester) was slightly elevated in transplanted kidneys (1.1) compared with normal healthy kidneys (0.8). Despite the practical problems produced by organ depth, respiratory movement, and tissue heterogeneity, these results demonstrate the feasibility of obtaining ³¹P magnetic resonance spectra from human kidneys.

Bretan et al.^{6,7} reported their clinical experience with pre-transplant assessment of renal viability using ³¹P MRS to study 40 renal transplant recipient patients (Figure 4). The purpose of their study was to develop and investigate the use of MRS in the clinical transplant setting by correlation of pretransplant MRS parameters with subsequent renal function. Kidneys were studied during simple hypothermic storage within their sterile containers using an external ³¹P MRS surface coil. Mean storage times were about 38 hours. Cold storage times did not correlate with subsequent clinical renal function. However,

Figure 3 Phosphorus-31 ISIS spectra of (a) the healthy normal kidney and (b) of the well functioning kidney transplant. Acquisition parameters: $TR = 2.0$ seconds, acquisition time = 1 hour, 90° pulse set for the region of interest, distance of the center of the volume of interest (VOI) from the 14 cm surface coil = 70 mm for normal kidney and 42 mm for transplanted kidney, size of the VOI is $25 \times 45 \times 55$ mm = 62 ml for normal kidney and $25 \times 50 \times 54$ mm = 68 ml for transplanted kidney. (Reproduced by permission of Springer-Verlag from Boska et al.⁵)

selected ^{31}P MRS data did. ATP was present in 11 kidneys and was associated with the best subsequent renal function. Only 36% of these patients required dialysis, compared with 71 patients without detectable ATP who required a posttransplant dialysis. Kidneys with ATP had the highest PME/Pi (Pi, inorganic phosphate) ratios; in general, the higher the PME/Pi ratio, the better the renal function posttransplant. The intracellular pH did not correlate with subsequent renal function. The authors suggested that MRS provided a better correlation with renal function after transplantation than existing methods.

Grist et al.⁸ used ^{31}P MRS to investigate the effects of rejection on renal transplants (Figures 5 and 6). The PDE/PME (PDE, phosphodiester) and Pi/ATP ratios in the transplants with rejection differed significantly from the corresponding metabolite ratios of patients without rejection. A PDE/PME ratio exceeding 0.8 had a sensitivity of 100% and a specificity of 86% for predicting rejection. A Pi/ATP ratio greater than 0.6 had a sensitivity of 72% and a specificity of 86% for predicting rejection. The authors concluded that ^{31}P MRS may be useful as a noninvasive method for evaluating renal metabolism during episodes of transplant rejection.

2 PROSTATE

2.1 Proton MRS of Prostate

Normal prostate has a very high concentration of citrate, a unique feature of this tissue related to the function of prostate cells to secrete citrate into the semen. Most of the MRS of prostate has focused on investigating changes of citrate associated with benign prostatic hypertrophy (BPH) and prostatic carcinoma. Schick et al.⁹ investigated the signal characteristics of citrate at low field strengths at 1.5 T using spatially selected spectroscopy and theoretical methods. In vivo localized spectroscopy of small volume elements (2 ml) using a double spin echo method within the prostate gland provided citrate signals.

Volume selected proton spectra with different echo times were recorded.

Thomas et al.¹⁰ performed ^1H MRS of normal and malignant human prostates in vivo (Figures 7 and 8). The results demonstrated that water-suppressed ^1H MRS spectra could be obtained from the prostate. Normal healthy prostate showed a large resonance from citrate. The spectrum from a malignant human prostate showed a much lower level of citrate. The results also suggested that the low concentration of citrate might be useful for the identification of prostate cancer.

Schnall et al.¹¹ performed localized ^1H MRS of the human prostate in vivo using an endorectal surface coil. High levels of citrate were observed in all regions of normal prostate and benign prostatic hypertrophy. The citrate levels in regions containing tumor were variable. The presence of high citrate levels in one case of prostate cancer was confirmed from extracts.

Schiebler et al.¹² reported high-resolution ^1H MRS of human prostate perchloric acid extracts (Figure 9). The citrate peak area was higher in benign prostatic hyperplasia than in adenocarcinoma. However, citrate peak areas from the normal peripheral zones were not significantly different from those found in adenocarcinomas. A sharp peak at 2.05 ppm that was seen in four out of thirteen adenocarcinoma samples and only one out of thirteen in the BPH samples was assigned to *N*-acetylneuraminic acid. Fowler et al.¹³ also obtained ^1H NMR spectra from perchloric extracts of tissue samples from human prostate. Statistically significant differences between the normals, the benign prostatic hypertrophy, and the cancer groups occurred for metabolite ratios of creatine, citrate, and phosphorylcholine. None of the ratios correlated with the Gleason grade of the cancer samples. Different sections of large tumors often yielded substantially different ratios.

Yacoe et al.¹⁴ reported in vitro ^1H MRS of normal and abnormal prostate cells (Figure 10).

Proton MRS was used to determine if cell strains derived from prostatic cancers could be distinguished from normal prostate. Prostatic cancer cells had lower concentrations of

Figure 4 Ex situ in vivo magnetic resonance spectrum of (a) a viable pediatric and (b) an adult kidney. PME, Pi, PDS (phosphodiester), and ATP (adenosine triphosphate) peaks are defined. (Reproduced by permission of Williams & Wilkins from Bretan et al.⁶)

citrate compared with normal prostate epithelium, but the differences were small and not statistically significant. However, both the cancer and normal prostate cells were washed, which may have removed diffusible citrate.

Kurhanewicz et al.¹⁵ performed ^1H MRS and enzymatic assays of human prostate adenocarcinomas and prostate DU145 xenographs grown in nude mice. The results showed that citrate concentrations in primary human adenocarcinomas were significantly lower than those observed for normal benign hyperplastic prostatic tissue. There was a 10-fold reduction of citrate associated with DU145 xenographs compared with primary prostate cancer. These findings support the hypothesis that citrate concentrations are low in prostate cancer.

Figure 5 Contiguous ^{31}P magnetic resonance spectra obtained from slices of kidney. Note the presence of significant PCr at the surface, consistent with muscle tissue. The deepest slice shows a large PME peak and little PCr, consistent with renal tissue. Peaks from left to right correspond to PMEs (a), Pi (b), PDEs (c), PCr (d) and γ - (e), α - (f), and β - (g) phosphates of ATP. (Reproduced by permission of Williams & Wilkins from Grist et al.⁸)

In the past several years Kurhanewicz, Vigneron and their colleagues have published a series of reports using ^1H MRSI of the prostate in a clinical setting. They have used an endorectal coil¹⁶ and a high spatial resolution technique.¹⁷ This

Figure 6 Phosphorus-31 magnetic resonance spectra from a patient with (a) a normally functioning renal allograft, (b) a patient with cyclosporine nephrotoxicity, and (c) a patient with moderate cellular rejection. Note the increase in Pi and PDE in the patient with rejection compared with the normal control subject or the patient with cyclosporine toxicity. PCr is a contaminant from extrarenal tissue. (Reproduced by permission of Williams & Wilkins from Grist et al.⁸)

Figure 7 Proton magnetic resonance spectrum prostate in a healthy 26-year-old subject with $TE = 40$ ms. The total acquisition time was 1.5 minutes. Resonance assignments: 1, 2, water and MDPA from the external standard, situated in the plane of the surface coil; 3, residual water; 4, spermine/creatine/PCr; 5, 6, the methylene protons of citrate; 7, methylene protons of spermine and lipids. (Reproduced by permission of the Society for Magnetic Resonance Imaging from Thomas et al.¹⁰)

Figure 8 Proton magnetic resonance spectrum of a malignant human prostate with binomial water suppression. Number of scans = 16; repetition time, 5 seconds; $TE = 80$ ms; total acquisition time = 80 seconds. The residual water and the resonances from the external standard were identified at 4.8 and 7.8 ppm, respectively. A 16-step phase cycling was used. Resonance assignments: 1, 2, external standard; 3, residual water; 4, 5, C-2 and C-5 protons of the citrate molecule; 6, 7, methylene protons of spermine and lipids. (Reproduced by permission of the Society for Magnetic Resonance Imaging from Thomas et al.¹⁰)

approach has been used to study the effects of hormone ablation¹⁸ and cryosurgery,¹⁹ and for the detection of local recurrence.^{20,21}

2.2 Phosphorus-31 MRS of Prostate

Kurhanewicz et al.²² reported the use of a ^{31}P MRS transrectal probe for studies of the human prostate (Figures 11–13). The preliminary results indicated that transrectal ^{31}P MRS may characterize ^{31}P metabolites in normal prostates, benign prostatic hyperplasia, and malignant prostates. The preliminary results suggested that malignant prostates are characterized by significantly decreased levels of PCr and increased levels of PME compared to healthy prostates. Thomas et al. evaluated some of the problems encountered with transrectal ^{31}P MRS of human prostate to determine the optimal conditions for these studies.²³ The authors investigated the reproducibility of ^{31}P MRS, regional differences of ^{31}P metabolites, the T_1 relaxation times, and metabolic alterations associated with disease. The PME/ATP ratio was highest in the upper region and lowest in the lower region. Similarly, the PDE/ATP ratio was highest in the upper region and lowest in the lower region. In contrast, the PCr/ATP was lowest in the upper region but was increased in the lower region.

The PME/ATP ratio of normal subjects (0.09 ± 0.1) was increased in the patients with BPH (1.5 ± 0.1) and significantly increased in patients with cancer (1.7 ± 0.2). The PCr/ATP ratio in normal subjects (1.5 ± 0.2) was not significantly

reduced in BPH, but it was reduced to 0.9 in prostatic cancer. The PME/PCr ratio in normal subjects was 0.7, was not significantly increased in BPH to 1.4 but was significantly increased in prostate cancer to 2.2.

Hering and Muller reported ^{31}P MRS and ^1H MRI of the human prostate with a transrectal probe.²⁴ Fourteen patients were evaluated with ^1H MRI and seven patients with ^{31}P MRS. The PME/ATP ratio was higher in patients with prostatic cancer.

Narayan et al. investigated the ability of ^{31}P MRS to characterize normal human prostate as well as prostate with benign and prosthetic hypertrophy and malignant neoplasms (Figure 14).²⁵ Normal prostate had PCr/ATP, PME/ATP, and PME/PCr ratios of 1.2, 1.1, and 0.9, respectively. Malignant prostates had PCr/ATP ratios that were lower than normal prostates. Malignant prostates had PME/ATP ratios that were higher than normal prostates.

Using the PME/PCr ratio it was possible to differentiate metabolically malignant prostates from normal prostates with no overlap of individual ratios.

2.3 Carbon-13 MRS of Prostate

Halliday et al. obtained high-quality, high-resolution proton decoupled natural abundance ^{13}C NMR spectra from various human tumors, including prostate (Figure 15).²⁶

Figure 9 (a) In vitro ¹H NMR spectra at 360 MHz, demonstrating a normal pattern with a large citrate peak seen in a sample of benign prostatic hyperplasia with a glandular predominance (C, citrate; L, lactate). Standard not shown. (b) In vitro ¹H NMR spectra at 360 MHz for adenocarcinoma showing the expected low citrate peak. Standard not shown. (Reproduced by permission of Williams & Wilkins from Schiebler et al.¹²)

Figure 10 Two-dimensional *J* resolved spectrum of an HClO₄ extract of a normal peripheral zone epithelial cell strain, obtained at 500 MHz. The chemical shift is resolved in the horizontal axis and the *J* coupling constant of complex peaks is resolved in the vertical axis. The complex peaks assigned to citrate (C) are pointed out. A one-dimensional projection in the chemical shift dimension is plotted at the top. (Reproduced by permission of Williams & Wilkins from Yacoe et al.¹⁴)

Figure 11 Phosphorus-31 magnetic resonance spectrum of a normal prostate from a normal subject (26 years old), *TR* = 20 seconds; *NS* = 100. (Reproduced by permission of the Society for Magnetic Resonance Imaging from Thomas et al.²³)

When prostatic adenocarcinoma was compared with adjacent hyperplastic tissue, the tumors were found to contain larger amounts of triacylglycerols, smaller amounts of citrate, and acid mucins. The citrate-to-lipid ratio appeared to differentiate malignant from nonmalignant prostates.²⁶ Halliday et al. obtained ¹³C NMR spectra from prostate tumor cell lines.²⁷ The results showed that the amount of taurine was increased, and tyrosine was decreased in androgen sensitive rat prostatic tumors in comparison to androgen responsive malignant or normal tissue. The authors concluded that the amount of these

Figure 12 Phosphorus-31 magnetic resonance spectra from human prostates in patients with (a) BPH and (b) prostatic cancer. (Reproduced by permission of the Society for Magnetic Resonance Imaging from Thomas et al.²³)

Figure 13 Phosphorus-31 magnetic resonance spectra from (a) upper, (b) middle, and (c) lower regions of the prostate. (Reproduced by permission of the Society for Magnetic Resonance Imaging from Thomas et al.²³)

amino acids discriminates androgen-sensitive from insensitive rat prostatic tissues. Sillerud et al. followed this up with an *in vivo* ^{13}C NMR study of human prostate (Figure 16).²⁸

High levels of citrate were measured in the human prostate *in vivo* as well as the tissue samples of human and rat prostate *in vitro*.

3 TESTICLE

3.1 Phosphorus-31 MRS of Testicle

Chew et al. investigated the clinical feasibility of ^{31}P MRS to assess the metabolic integrity of the human testicle (Figures 17 and 18).²⁹ The PME/ATP ratio was greatly reduced in the

Figure 15 Natural abundance proton decoupled 100.6 MHz ^{13}C NMR spectrum of (a) human prostate with benign prostatic hypertrophy. This proton decoupled spectrum was taken from 2.24 g of tissue, at a temperature of 310 K, with a total of 17 271 scans. (b) A spectrum of poorly differentiated adenocarcinoma of human prostate from the same individual as (a), taken from 3.51 g of tissue with the same parameters, except for the use of 11 241 scans in total. It should be noted that peak 11 is truncated. Assignments for the numbered resonances are given elsewhere.²⁶ These spectra are representative of seven hyperplastic prostates, three of which contained adenocarcinoma, plus a fourth sample of adenocarcinoma, with the following exception: lactate was increased relative to the control tissue only in the depicted case and resonances from acidic mucins were not present in all of the tumors. (Reproduced by permission of Williams & Wilkins from Halliday et al.²⁶)

abnormal testicle; furthermore, the PME/ATP ratio was also reduced in patients with primary testicular failure.

In patients with azoospermia, there were significant differences in the same peak area ratios between patients with primary testicular failure and those with chronic tubular

Figure 14 *In vivo* ^{31}P magnetic resonance prostate spectra. (a) Normal volunteer, (b) patient with BPH, and (c) patient with prostatic cancer. (Reproduced by permission of Williams & Wilkins from Narayan et al.²⁵)

Figure 16 Proton decoupled, natural abundance 100.614 MHz ^{13}C NMR in vitro spectrum from 3.88 g of human benign hypertrophic prostate tissue sample. This spectrum is the average of 13 600 scans at a temperature of 283 K. The signal at 165 ppm is from 15 μl of a 0.15 M ^{13}C sodium cyanide standard. (Reproduced by permission of Williams & Wilkins from Sillerud et al.²⁸)

Figure 17 Characteristic ^{31}P magnetic resonance spectrum from the in vivo normal human testicle. Present are the three peaks due to ATP, small signals from PDE and Pi, and a large contribution from the PME peak. This spectrum was acquired with 400 signals averaged in 13.5 minutes. (Reproduced by permission of the Radiological Society of North America from Chew et al.²⁹)

obstruction. Bretan et al. compared ^{31}P MRS of human testicle with conventional semen analysis.³⁰ The glycerophosphorylcholine (GPC)/total phosphate ratio in azoospermic men

after vasectomy significantly differed from the control GPC/total phosphate ratio, which appropriately reflected complete vasal occlusion. The results suggested that a significant portion of seminal GPC is derived from epidymal secretion and that ^{31}P MRS is useful for monitoring GPC/total phosphate levels when assessing epidymal function in male infertility.

4 UTERUS

High-resolution ^1H MRS was used as an adjunct to conventional and histological diagnosis of cervical neoplasia.³¹ Cervical biopsy specimens were examined with ^1H MRS and the results compared with histology. A high-resolution lipid spectrum was observed in 39 of 40 invasive carcinomas whereas 119 preinvasive samples showed little or no lipids but were characterized by a strong unresolved peak between 3.8 and 4.2 ppm. Peak ratios of the methylene/methyl and the unresolved/methylene resonances allowed accurate distinction between invasive and preinvasive malignancy.

Liver, Pancreas, Spleen, and Kidney MRI

David Stark and Ashley Davidoff

University of Massachusetts, MA, USA

1 INTRODUCTION

The upper abdomen presents unique diagnostic challenges. Numerous organs with diverse physiological functions are in close proximity with each other, abut the cardiopulmonary system through a thin diaphragm, and have open contact with the dependent organs of the pelvis. Thus, tumors, inflammatory disease, and other pathology of the upper abdomen may present clinically with symptoms attributable to an organ involved only secondarily, or they may appear to arise from the thorax or pelvis, leading the clinician away from the primary problem. Imaging of the abdomen is confounded by its large anatomic area, the mobility of the organs and their fluids, and the presence of tissues of varying imaging characteristics.

This article briefly introduces the advantages and limitations of magnetic resonance imaging (MRI) methods as applied to the evaluation of abdominal cancer. After the technical introduction, which provides an understanding of the philosophy of probing the abdomen for known or unsuspected disease, the remainder of the discussion reviews the MRI characteristics of the major upper abdominal neoplasms.

Virtually all diagnostic medicine, and certainly diagnostic imaging, is guided by three hierarchical objectives:

1. detection of disease;
2. characterization of disease; and
3. staging of disease.

Detection itself is the most important challenge, as it begins with the patients themselves deciding whether a symptom is sufficiently abnormal to warrant a visit to the doctor. After several clinical steps, imaging is most commonly used to determine whether an anatomic area (head, neck, chest, abdomen, pelvis, or musculoskeletal system) or physiologic organ system (e.g. hepatobiliary system) is normal or abnormal. This simple, binary decision is critical in selecting patients for more intensive investigation at considerable expense and no small risk of iatrogenic complications.

Characterization of disease commences once an abnormality is found. In the abdomen, nearly all patients develop benign masses if they live long enough (e.g. renal cyst or nodular hyperplasia of the prostate). Where imaging for other reasons results in detection of these benign masses, imaging must also solve the diagnostic dilemma it created and, at low cost, identify these lesions as benign and of no clinical significance.

Staging is essential to determining prognosis and therapy once treatable disease has been characterized. In many ways, staging is a subset of detection as it is the process by which multiple lesions are discriminated from a single abnormality, and the extent of disease within an organ or spread to adjacent

Figure 1 Normal abdomen. T_1 -weighted spin echo image at the level of the pancreatic head shows a normal common bile duct, gall bladder, hepatic artery, and confluence of the splenic and portal veins. The absence of a motion artifact and the low signal intensity of kidneys relative to that of the liver are clues that this is a short TE sequence

areas is measured. Since staging often involves monitoring of treatment, it presents unique problems because the background normal structures may be altered by surgery, radiation, or progression of the disease itself. As society raises ethical and economic questions concerning the merit of treating various conditions, imaging becomes more important as a noninvasive low-cost method of determining which treatments are appropriate and effective.

2 IMAGING TECHNIQUES

MRI is similar to computerized tomography (CT) in providing a full field of view of the abdomen, and a permanent record of the entire examination, to a comparable level of anatomic detail (spatial resolution). MRI has the further advantage of allowing selection of sagittal, coronal, or oblique planes of section. However, in the abdomen virtually all imaging is performed in the transverse plane (see Figure 1).

MRI in the 1990s, like CT in the 1970s, is getting faster, with the expectation that speed will solve the problem of motion. Debate rages concerning the optimal methods for obtaining T_1 or T_2 contrast and the best signal-to-noise ratio (S/N) per unit time. These technical details are addressed elsewhere in this volume.

3 IMAGE QUALITY

Specific magnetic resonance (MR) pulse sequences and their user-selectable timing parameters are of utmost importance for lesion–liver contrast and image quality. MR image quality can be quantified by calculating the lesion–liver contrast-to-noise ratio (CNR) and the liver S/N.¹ Motion artifacts contribute

most to (systematic) noise in abdominal imaging. Vascular ghost artifacts arising from the aorta and inferior vena cava may obscure focal hepatic abnormalities, especially in the left lobe. Changing the phase-encoding direction results in artifacts projected outside the region of interest.^{2,3} Signal averaging or implementation of presaturation pulses are highly effective methods of motion artifact reduction in the upper abdomen.

The CNR is an effective parameter for quantitating pulse sequence performance with respect to lesion detection. A useful rule is that spleen–liver CNR will, on average, match cancer–liver CNR. This rule holds for all pulse sequences, on all machines, and at all field strengths, since, on average, cancer and spleen have the same proton density, T_1 and T_2 .

Thus, the spleen can serve as a reference signal intensity, and the spleen–liver CNR will be predictive of pulse sequence performance for liver cancer detection.

4 PULSE SEQUENCE PERFORMANCE

Theoretical calculations suggest that the optimal pulse sequence for hepatic tumor detection varies with field strength. However, clinical results have not confirmed any significant field strength differences. Performance variations due to gradients, other hardware, and software appear to be more substantial. The dominant factor appears to be the level of commitment of the practicing radiologist who implements and maintains quality imaging protocols tailored to the specific machine and its generation (upgrade level). In an area such as the abdomen, of which relatively few MRI examinations are conducted, the necessary expertise and attention to detail is too often lacking.

Properly performed T_1 - or T_2 -weighted sequences yield comparable CNR values and hence efficacy at liver cancer detection. Cancer or lymphoma of the spleen is poorly detected by any method, since cancer and spleen have the same proton density, T_1 , and T_2 , on average. T_1 -weighted sequences generally offer greater S/N per unit time than do T_2 -weighted sequences. This fact, combined with excellent fat–tissue T_1 contrast, leads to the choice of short TE T_1 -weighted sequences for imaging the pancreas, kidneys, adrenal glands, and the remainder of the retroperitoneum and mesentery.

While T_1 -weighted images offer superior anatomic resolution and are generally superior for detection of abdominal pathology, it is well established that T_2 -weighted sequences are preferred for tissue characterization, especially in the liver and adrenal glands. Less is known about the kidney, where both benign (solid or cystic) and malignant lesions are also common.

4.1 Contrast Media

Parenchymal tissue contrast is enhanced by intravenous or arterial administration of magnetopharmaceuticals. Commonly gadolinium diethylenetriaminetetraacetic acid, Gd-DTPA, (Magnevist) or the newer nonionic contrast agents, such as Gd-DTPA-BMA (Omniscan) or GdDO3A (ProHance) are given by the intravenous route. These agents are designed for rapid excretion and do not significantly interact with body physiology. Binding to blood proteins or cells is negligible. Excretion is by passive glomerular filtration. Thus, these agents, introduced to

the blood stream, will penetrate capillaries in the body and have an extracellular distribution, although in the brain they are limited to the vascular space by the blood–brain barrier. It is the molecular weight of these agents (less than 1000 Da) that determines their diffusion into the extracellular space of the abdominal organs.

Intravenous contrast agents are concentrated in the renal tubules, distinguishing functioning renal tissue from all but the most vascular kidney tumors. Unfortunately, in the liver, spleen, and pancreas, the blood supply, capillary permeability, and capacity of the extracellular space of tumors is quite variable. The kinetics and degree of enhancement of the tumors is often described in general terms such as ‘hypovascular’ or ‘hypervascular’. Unfortunately, enormous biological variation exists, and tumors of a common cell type (e.g. colon adenocarcinoma) show wide variations in enhancement characteristics.

Efforts to enhance selectively liver parenchyma and improve the contrast between normal liver and cancer include rapid (‘dynamic-bolus’) intravenous infusion to exploit the dual (portal venous and hepatic arterial) vascular supply of normal liver as opposed to cancers, which are typically supplied by arteries and may have fewer vessels than normal liver. Dissatisfaction with intravenous techniques has stimulated attempts to administer contrast agents at angiography via selective cannulation of the hepatic artery or via the superior mesenteric artery, looking at the portal venous phase of contrast circulation. This latter approach may improve tumor–liver image contrast, and some authors have claimed improved sensitivity for detecting liver lesions. However, due to variations in the portal venous perfusion of the liver, nonneoplastic perfusion inhomogeneities create numerous false-positive diagnoses of cancer, lowering specificity and limiting the value of this technique for planning therapy.

For more than a decade, investigators have attempted to adapt cholegraphic agents, taken up by hepatocytes and excreted into the biliary system, for use in the detection of liver cancer.⁴ Similarly, colloidal or particulate magnetopharmaceuticals have been used to target the normal hepatic Kupffer cells in an attempt to contrast liver against cancer, which does not show phagocytic uptake of magnetic particles. Unfortunately, attempts to target particulate agents in bulk to normal liver have been complicated by toxic side effects. Newer superparamagnetic iron oxide agents under development may show improved safety profiles.⁵

5 THE LIVER

5.1 Metastases

The liver is the most common organ in the body to which cancer spreads from primary disease elsewhere. Gastrointestinal neoplasms, including those in the pancreas, nearly always involve the liver before metastasizing to other organs. In addition, breast, lung, renal, and ovarian and other common malignancies spread hematogenously, lymphatically or transperitoneally to the liver. Indeed, liver failure is one of the most common causes of death in cancer patients, and liver metastases serve as a basis for determining prognosis and monitoring therapy.

Serologic studies of liver function, including enzymes leaked into the blood stream when the liver is injured [serum

glutamic oxaloacetate transaminase, (SGOT), serum glutamic pyruvic transaminase (SGPT), and alkaline phosphatase], have such poor sensitivity and specificity that they cannot be justified for use as an independent diagnostic test. When metastatic cancer to the liver is suspected or a reasonable risk exists, imaging must be performed. Unfortunately, imaging also has its limitations and pitfalls.

Metastatic spread of cancer is thought to begin as a single cell or a small cluster of cells, well below the resolution limit of imaging. Indeed, imaging cannot reliably detect liver lesions smaller than 5 mm in size. As a metastasis grows exponentially it is therefore submillimeter in size for the vast majority of its 'life cycle' before it enlarges to the point of causing symptoms and ultimately killing the patient. Therefore, it is obvious that the majority of metastases present in an individual, or speaking epidemiologically, the majority of metastases present in a population, are below the threshold size for detection by any means.

5.2 Imaging: Detection

Liver cancer detection does offer clinically useful information because most patients with metastatic cancer have multiple lesions, some of which are sufficiently large (>1 cm diameter) to be detected reliably. The accuracy of imaging for detecting liver metastases is the subject of endless disputes and revision of the radiological literature. The major problem with the literature is the lack of suitable 'gold standards'. It is simply impossible to collect a large series of patients for whom autopsy and histologic confirmation of imaging findings are available. Thus, radiologists frequently resort to comparative studies where one modality is compared to another, and a third technique (such as surgery) or a third imaging modality is used as the arbiter of 'truth'. Such comparative studies consistently overestimate the accuracy of detection of liver lesions.⁶⁻⁹

It is now generally accepted that MRI is the best test, followed by CT, ultrasonography, and then angiography. CT angioportography (CTAP) techniques are equal to or slightly better than MRI; however, the angiographic CT methods are generally not available and are nearly 10 times more expensive. Therefore, when the clinician is able to focus the diagnostic question of the detection of liver metastases, MRI is now the preferred technique. Unfortunately, clinicians often have mixed objectives and request inspection of the adrenal glands, retroperitoneum, and other abdominal organs. As a practical matter, in such unfocused clinical situations, ultrasonography or CT are preferred, despite their inaccuracy, as widely available, cheap, and, arguably, acceptable (i.e. 'cost-effective') compared to MRI.

In summary, for patients at risk of metastatic cancer it is an economic and public policy issue whether the best test (MRI) is made available. Given the cost of misdirected cancer therapy in patients with undiagnosed metastases (in societies where cancer treatment is available), it is likely that diagnostic imaging pays for itself. Unfortunately, neither MRI nor CT is available to many patients. For a variety of nonscientific reasons, doctors often accept ultrasonography as the primary screening test, notwithstanding the hidden costs of false-negative and false-positive examinations.

The dominant worldwide use of ultrasonography for liver imaging may in fact be cost-effective, as this rapid and inexpensive method does reliably identify the majority of patients

Table 1 Relaxation Times for Liver, Hemangioma, Metastases, and Hepatocellular Carcinoma at 0.6 T^a

Tissue	T_1	T_2
Normal liver	499 ± 140	48 ± 11
Hemangioma	1010 ± 497	143 ± 51
Metastases	691 ± 100	71 ± 21
Hepatocellular carcinoma	569 ± 133	87 ± 17

^aValues are the mean ± SD calculated from four or more spin echo measurements.

having metastatic cancer. Since the treatments available have such a poor outcome, is it any wonder that misdiagnosis and inappropriate therapy combined do not noticeably alter this miserable outcome? Despite government pressure to sacrifice health and life that is not measurable or statistically cost-effective, medical ethics dictates that in those cases having a solitary or questionable liver lesion at ultrasonography, CT should be made available. Setting aside economic issues, state-of-the-art oncologic practice requires use of either CT or MRI to screen for liver metastases in the abdomen.

5.3 Lesion Characterization

MRI is more likely than CT to demonstrate internal nodular structure, rings and hemorrhage. In particular, T_2 -weighted MR images are useful as they show edema at the border of active lesions which may be manifested as rings or as geographic zones of increased signal intensity. T_1 -weighted images are less sensitive to edema; as a result, metastases are virtually always the same size or larger on T_2 -weighted images.

5.4 Staging

Staging of hepatic neoplasms principally involves identifying the lobe and segment of disease. Patients with larger tumor burdens and receiving chemotherapy can be monitored by scan-to-scan comparison of tumor diameters or estimates of tumor volume. Some idea about the extent of differentiation that is possible is given by Table 1.

Surgical approaches to hepatic metastases depend primarily on confidence that all of the tumors have been identified. If there is reason to believe that a solitary metastasis exists or that a cohort of a few similar sized lesions represent the only disease in the liver, then the question of resection depends upon the functional hepatic reserve and the technical ability to remove the lesions. Lesions invading an adjacent structure, such as the diaphragm or inferior vena cava, or lesions in difficult areas, such as the porta hepatis, make surgery challenging and risky. Undoubtedly, the greatest risk to resective therapy is undiagnosed residual disease.

6 HEPATOCELLULAR CARCINOMA

Also known as 'hepatoma', primary malignancy of hepatocytes [i.e. hepatocellular carcinoma (HCC)] comprises 1% of all cancers in the USA. Worldwide, variation in nutritional fac-

tors and the incidence of viral hepatitis^{10,11} account for major differences in the incidence and nature of HCC. It is far more common in Japan, the rest of Asia, and sub-Saharan Africa in association with chronic viral hepatitis. Articles can be found in the literature citing a wide range of sensitivity, specificity, and overall accuracy for ultrasonography, CT and MRI.^{13,14,15} It is evident that HCC is more difficult to detect with any of the imaging methods than is metastatic cancer. The principal reason for this difficulty is that HCC most often occurs against a background of chronic hepatitis, fatty liver and cirrhosis.^{11–14}

Fatty change within malignant hepatocytes serves to decrease tumor–liver contrast on conventional MR images, although the presence of fat can be exploited to increase contrast if chemical shift selective techniques are used.

Ongoing regeneration and areas of nodular hyperplasia serve to mask or mimic hepatoma. Bands of scar tissue in the liver have increased water content, and the long T_1/T_2 signal intensity characteristics are very similar to hepatoma.

6.1 Lesion Characterization

Characterization of hepatoma and discrimination from metastatic cancer or benign hepatic masses is rarely possible with ultrasonography, CT, or scintigraphy. MRI, however, has the ability to detect three features characteristic of hepatoma. Each of these features is present in approximately 30% of hepatomas, and therefore one or more features can be found in a majority of cases.

First, a capsule of compressed liver or scar tissue may create a sharp boundary with adjacent liver tissue. The capsule has long T_1 /long T_2 signal intensity characteristics, and is usually best seen on T_1 -weighted images. The capsule must be distinguished from low signal intensity blood vessels on T_1 -weighted spin echo images. Hepatic adenoma may also show peripheral capsules indistinguishable from those of hepatoma. However, hepatic adenoma is an unusual tumor with different demographics. Tumor and capsules can be distinguished from the rings of metastases, as the latter are better seen on T_2 -weighted images and are not well seen at all on T_1 -weighted images. Images from a hepatic adenoma study are shown in Figure 2.

Second, hepatomas accumulate intracellular triglyceride. Fatty accumulation can be detected using a variety of chemical shift methods such as phase contrast frequency-selective imaging. Although fatty accumulation may occur in injured hepatocytes in other conditions, including adenoma, focal nodular hyperplasia, hepatitis, and dietary disturbances, it is usually possible to distinguish focal fatty infiltration from fat within a mass, as the latter displaces normal blood vessels, while focal fat infiltration usually does not.

Third, hepatoma has a propensity to grow into hepatic and portal veins, and MRI is able to demonstrate this morphology to advantage. Certainly ultrasonography also has this capability; however, the ability of ultrasonography to distinguish the solid tumor from adjacent liver makes it more difficult to follow the tumor into vessels.¹⁷

7 BENIGN DISEASE: CAVERNOUS HEMANGIOMA

Hemangioma is a vascular malformation characterized by a cavernous collection of blood spaces (Figure 3). Blood flow is

Figure 2 Hepatic adenoma. (a) A CT scan enhanced with bolus infusion of iodinated contrast media shows a large enhancing lesion in the left hepatic lobe. This finding is nonspecific and resembles cancer or any other solid neoplasm. (b) A catheter angiogram suggests a benign solid tumor, most likely hepatic adenoma. (c) MRI (SE 1500/100) shows a heterogeneous mass that is isointense with the spleen, consistent with any solid neoplasm; surgery confirmed the diagnosis

very slow and virtually undetectable, except for the occasional peripheral site of venous entry. Hemangioma is exceedingly common in both sexes and all races around the world. Approximately 15–20% of the adult population has such a lesion.⁸

Figure 3 Cavernous hemangioma of the liver. (a) A CT scan shows a 3 cm lesion in the posterior segment, right hepatic lobe, with a hypodense appearance identical to cancer. (b) MRI (SE 300/15) shows the lesion to have a low intensity, similar to cancer (very slightly darker than the spleen). Note a second, 1 cm lesion in the anterior segment not seen on the CT scan. (c) MRI (SE 2400/180) shows the lesions to be hyperintense relative to spleen, and nearly isointense with cerebrospinal fluid; this is consistent with blood in cavernous hemangiomas. (d) Lesions as small as 3 mm diameter can be characterized by MRI

7.1 Lesion Characterization

MRI has been remarkably successful in identifying the fluid content of cavernous hemangiomas by its long T_2 relaxation time (Table 1).^{15,16} Long TE spin echo images, which reduce the signal intensity of solid tissue relative to fluid, show cavernous hemangiomas, cerebrospinal fluid, bile, and gastric contents as extremely bright structures. Properly performed, with TE in excess of 120 ms and successful suppression of motion artifact, cavernous hemangiomas are homogeneous and sharply circumscribed on the MR image. Tumors, on the other hand, are ill-defined, heterogeneous, and lower in signal intensity due to their gelatinous (solid) make-up.

Contrast-enhanced blood-pool studies provide an alternative method of identifying hemangiomas and other vascular lesions. CT uses iodine based diagnostic pharmaceuticals; scintigraphy uses technetium-labeled red blood cells, and MRI uses the paramagnetic agent Gd-DTPA. In addition, iron oxide particles and other magnetic contrast media have

been shown to be effective blood-pool markers. The concept behind these studies depends principally on the kinetics and distribution of the vascular agents. Cavernous hemangiomas tend to enhance uniformly over 5–30 min and may retain contrast longer than the circulating blood pool. Solid tumors show more rapid wash-in and wash-out of the contrast agent and usually show less peak enhancement than do cavernous hemangiomas. As these findings depend upon the cardiac output, circulation time, timing of contrast administration, and the specifics of the perfusion pattern of the vascular malformation, contrast-enhanced studies are less predictable than plain T_2 -weighted MRI. Nevertheless, MRI can be used in both methods.

Controlled studies have shown that MRI can discriminate cavernous hemangioma from solid neoplasm with an overall accuracy of 90%. If, in addition to this T_2 -weighted technique, a contrast study is done, the accuracy increases further. With MRI one can perform both an unenhanced and enhanced scan within a single 1-h examination.

8 THE PANCREAS

Adenocarcinoma is a malignant mucinous neoplasm of the pancreas that arises from the ductal epithelium. It is the fourth most common cause of death from cancer in the USA and accounts for 3% of all cancers. Adenocarcinoma represents 75% of nonendocrine pancreatic malignancies. The disease usually affects people over the age of 70 years, with a male/female ratio of 1.5:1.0. Proposed etiologic factors include cigarette smoking and coffee consumption, alcohol consumption and dietary intake of fat, protein and a high number of calories.^{7,18,19}

Disease states of the pancreas that are reportedly associated with the development of pancreatic carcinoma include diabetes mellitus and familial pancreatitis. The etiologic association with chronic pancreatitis is not clear.

Because the pancreas is not encased by a capsule, early spread into the surrounding retroperitoneal fat is common. Local structures then become involved, including the portal vein, superior mesenteric vein, splenic vein, gastroduodenal artery, bile duct and duodenum. Local lymph-node involvement and hematogenous spread to the liver via the portal vein are also seen.

8.1 Imaging: Detection

Lesions in the head of the pancreas are generally visualized by both ultrasonography and CT. The former is limited by surrounding bowel gas or obesity in about 30% of patients. Maneuvers such as altering respiration, filling the stomach with water, placing the patient in the upright position and repeat scanning are helpful. Lesions in the tail of the pancreas are difficult to detect by ultrasonography, but visualization can be improved by using the spleen as a window. With CT, tail and body lesions are sometimes obscured by a partial volume artifact from a bowel not filled with contrast. Intraoperative ultrasound scanning is very sensitive to small and impalpable tumors, particularly for small, functioning tumors such as insulinomas.

MRI has little or no role at the present time due to inferior anatomic resolution and no better contrast than ultrasonography or CT.

8.2 Characterization

Ultrasonography, CT, and MRI are equally nonspecific in distinguishing pancreatic cancer from benign masses. Pancreatitis is the most important differential diagnosis. In most cases, radiologically guided fine-needle aspiration biopsy (FNAB) is necessary for diagnosis.

9 THE SPLEEN

The spleen rarely causes clinical symptoms and is most often imaged as a bystander to a study directed at another abdominal organ. Trauma and suspected rupture is the most frequent indication for imaging the spleen itself. While MRI would be preferred, CT is usually selected because of its availability and resistance to motion artifacts.

Oncologic disease within the spleen is infrequently identified, even though more than half of patients with widespread malignancy may have splenic involvement at autopsy. Melanoma probably accounts for most of the metastases found in the spleen, although various studies have described the origin of metastases, in decreasing order of frequency, as lung, prostate, colon, stomach, melanoma, ovary, and pancreas.

9.1 Lymphoma

Imaging of lymphoma has traditionally been insensitive to splenic involvement. Splenic size is unreliable, as one-third of patients with splenomegaly do not have lymphomatous involvement, and one-third of patients without splenomegaly have such an involvement. In patients with aggressive disease, such as the poorly differentiated nodular type, involvement becomes probable, but not necessarily visible.²⁰

Ultrasonography, CT, and scintigraphy have unsatisfactory accuracy rates, ranging between 54% and 75%. MRI is beginning to show some promise. When the water content of lymphoma is high, such as in the large lesions of histiocytic lymphoma, they become detectable on T_2 -weighted sequences. MRI using superparamagnetic iron oxide is showing promise in demonstrating splenic involvement, but these research findings need further clinical verification.²¹

10 THE KIDNEY

Renal disease, like diseases of the liver and pancreas, can be divided between diffuse and focal processes. Most diffuse disease is inflammatory or metabolic in nature.

Solid renal masses are cancers until proven otherwise, usually at the expense of nephrectomy given the habit of urologists to avoid referral of patients for FNAB, a less expensive alternative practice by radiologists. Since the aging population at risk of cancer has a high prevalence of benign simple cysts, it has been a challenge to identify benign lesions noninvasively, in order to save good kidneys from the knife. Unfortunately, features demonstrable by ultrasonography, CT, and MRI add little to the low pretest probability of malignancy. The few cancers picked up as cystic structures with nodular irregularities or septations by ultrasonography, calcifications or density changes on CT, or hemorrhage on MRI are outnumbered by similar findings in nonmalignant cysts falsely diagnosed as positive for malignancy.

While the identification of renal cysts by MRI should be as straightforward as identification of hepatic hemangioma, comparable research has not been performed to establish quantitative or qualitative criteria. Furthermore, renal cell carcinoma is more difficult than other cancers to distinguish from cysts because of its hypervascularity, tendency for necrosis, and the resultant long T_1/T_2 , approaching that of cysts.

MRI studies in the kidney have largely consisted of anatomic descriptions recapitulating the findings known from CT, albeit less clearly. The sole application of MRI to the diagnosis and management of renal disease is inspection of the draining veins for extension of tumor. For all other questions, ultrasonography and CT are preferred. As a result, very little renal MRI is practiced.

11 SUMMARY

Abdominal imaging is historically anatomic, based on the delineation of high contrast fatty tissue boundaries. Ultrasonography and CT are widely available, familiar to clinicians, competitive in diagnostic quality, and cheap. MRI of the abdomen is best established in the liver for detection and differential diagnosis of focal masses.

1 INTRODUCTION

Superb soft tissue contrast resolution and multiplanar imaging capability have placed MR imaging in an eminent position in the evaluation of pelvic anatomy and pathology. In the male pelvis, much work has been performed in studying the prostate gland, seminal vesicles, testes, penis, and urethra. While the results of MR imaging in these areas were promising from the very beginning, these applications are still wrapped in controversy, and the indications are not generally accepted by many clinicians. As MR techniques keep evolving and overall image resolution is improved, MRI is gaining recognition and converting many skeptics into ardent advocates.

2 PROSTATE GLAND

2.1 Anatomy

The mature prostate is composed of both glandular and non-glandular tissue. The glandular portion is differentiated into three major zones: peripheral (70%); central (25%); and transition (5%) zones.¹ A small amount of glandular tissue is also present in the periurethral glands. Zonal differentiation is clinically significant because most (68%) prostate carcinomas arise in the peripheral zone whereas benign prostatic hyperplasia (BPH) usually originates in the transition zone.² Nonglandular tissue within the prostate includes the urethra and anterior fibromuscular stroma.

The normal prostate gland demonstrates a homogeneous intermediate signal intensity on T_1 -weighted images, regardless of patient age or magnetic field strength; T_2 -weighted images are necessary to delineate the zonal anatomy of the prostate (Figure 1).³ The peripheral zone is of high signal intensity, equal to or greater than that of the adjacent periprostatic fat. In contrast, the central zone has a lower signal intensity than the surrounding peripheral zone.³ These differences in signal characteristics are thought to be related to the presence of striated muscle and fewer glandular elements in the central zone.³ The transition zone also has a lower signal intensity than the peripheral zone. The signal intensities of the central and transition zones are similar at all imaging parameters, and the two can be differentiated only by knowledge of their respective anatomic locations.³ On Gd chelate-enhanced T_1 -

Figure 1 Prostate gland, normal anatomy: T_2 -weighted image, endorectal coil, coronal plane of section. The peripheral zone (P) of the prostate gland demonstrates homogeneous high signal intensity. Seminal vesicles (SV) are seen cephalad to the prostate gland. They are convoluted in nature and have a grape-like appearance

weighted images, the zonal anatomy of the gland is depicted but not as consistently as on T_2 -weighted images.⁴

2.2 Pathology

2.2.1 Congenital Anomalies

Agenesis and hypoplasia of the prostate are frequently encountered with other congenital anomalies of the genitourinary tract. While MRI can establish the diagnosis, this frequently is an associated finding and not the clinical reason for the study.

Congenital cysts of the prostate are the most common anomalies of this gland. Prostatic utricle and Müllerian duct cysts are midline structures that arise at the level of the verumontanum and extend cephalad (Figure 2). Their signal intensity is nonspecific and depends on the nature of their content, ranging from serous to proteinaceous and hemorrhagic fluid.⁵

2.2.2 Inflammatory Disease

MR imaging does not play a role in the diagnosis of prostatic inflammatory disease. When discovered incidentally, acute prostatitis will demonstrate diffuse glandular enlargement and the peripheral zone sometimes exhibits a low signal intensity on the T_2 -weighted image.⁶ Thus far, there is only limited experience in MR imaging of prostate abscess. If this diagnosis is clinically suspected, transrectal ultrasound (TRUS) or CT should be the modalities of choice.

2.2.3 Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is a glandular and/or stromal proliferation in the transition zone and periurethral glands. The prostate gland is enlarged, and often the hyperplastic tissue is separated from the compressed peripheral zone

Figure 2 Prostatic utricle: T_2 -weighted image, coronal plane of section. The utricle (U) is seen as a midline cyst of high signal intensity extending superior to the verumontanum. In the right peripheral zone, the low signal intensity region is a focus of prostate cancer (C). E, right ejaculatory duct; CZ, central gland

tissue by the surgical pseudocapsule (Figure 3). MR imaging of BPH includes a spectrum of findings, based on the varying histologic composition and depending on the imaging sequence utilized.⁷ Although MRI provides excellent morphologic definition of BPH, it is not possible to differentiate benign from malignant disease of the prostate.

The multiplanar imaging capability of MRI allows accurate volumetric measurement of the hyperplastic prostate gland and is especially useful in glands greater than 100 g, where ultrasound is limited in accuracy.⁸ Because of its accuracy in volumetric measurement and depiction of zonal anatomy, MR imaging has been used in the follow-up of patients on androgen deprivation therapy in order to monitor the changes in gland size and in differential volume reduction in zones of the gland.⁹

2.2.4 Prostate Carcinoma

Cancer of the prostate is the most common cancer in men and ranks as the second most common cause of cancer death

Figure 3 Benign nodular hyperplasia: T_2 -weighted image, coronal plane of section. The prostate gland is enlarged. The heterogeneous signal intensity is secondary to benign nodular hyperplasia. A large hyperplastic nodule (*) protrudes into the urinary bladder (B)

in American men.^{2,10} MR imaging is not applicable for the detection of prostate carcinoma. The strength of MRI is in the staging of biopsy-proven prostate cancer, although this application continues to be controversial and is a subject of numerous ongoing investigations. On T_2 -weighted MR images, prostatic carcinoma (PCa) is most commonly shown as a decreased signal intensity area within the high-signal-intensity normal peripheral zone. The detection of PCa on MRI is applicable only to the tumors located in the peripheral zone. The normal low or heterogeneous signal intensity of the transition and central zones precludes tumor detection.¹¹ Even in the peripheral zone, tumor detection may be hampered by postbiopsy changes (Figure 4).¹¹ Depending on the time interval between biopsy and MRI scan, the biopsy changes may cause either under- or overstaging of tumor presence and extent. Recent studies have demonstrated that MRI should not be performed for at least 2 weeks after biopsy.¹² The finding of low signal intensity within the peripheral zone is not specific for prostate cancer.¹³ A number of other etiologies such as chronic prostatitis, dystrophic changes, scar, previous trauma, postbiopsy hemorrhage, radiation, and hormonal changes can all cause low signal intensity within the peripheral zone.¹³

Recently, *in vivo* MR spectroscopic imaging of the prostate gland has been developed to increase the specificity of cancer detection in the peripheral zone. This three-dimensional proton spectroscopic technique allows the simultaneous acquisition of multiple spectra from the prostate gland with a tissue voxel resolution down to 0.24 ml.^{14,15} Since the metabolic changes of prostate cancer cause an increase in choline and a decrease in citrate levels, the ratio of the area under the choline spectroscopic peak to that under the citrate peak is increased in areas of cancer. The increased choline/citrate ratio in areas of prostate cancer enables the differentiation of cancer from the other causes of low T_2 signal in the peripheral zone listed above (Figure 5).¹⁶ In addition, the ability to

Figure 4 Postbiopsy hemorrhage: T_1 -weighted image, transaxial plane of section. In this patient, hemorrhage after a prostate biopsy is seen as increased signal intensity diffusely in the peripheral zone (PZ) and more focally in the right central gland (CZ). Normally on T_1 -weighted images, the entire prostate shows homogeneous intermediate signal intensity

estimate the spatial extent of prostate cancer has important implications for assessing the efficacy of various cancer treatments.¹⁷

Prostate cancer, particularly the mucinous type, can demonstrate high signal intensity indistinguishable from the surrounding peripheral zone.¹⁸ While prostate cancer detection rates as high as 92% have been reported,¹¹ the results of large multicenter studies are disappointingly low, with only 60% of lesions greater than 5 mm in any one dimension being detected on MRI scans.¹⁹ Attempts have also been made to measure tumor volume by MRI. As with ultrasound, the results are inaccurate, and smaller lesions are overestimated in 44% of patients and larger lesions underestimated in 55% of patients.¹⁹

Prostate cancer staging can follow either the TNM or Jewitt classification.²⁰ The TNM stage 1 or Jewitt stage A are tumors not applicable to MRI detection. Most of those cancers are within the transition zone, the area where MRI can neither depict nor stage the disease. TNM stage 2–Jewitt B disease in-

Figure 5 MR spectroscopic imaging of the prostate gland: transaxial T_2 -weighted image and MR spectra. The spectrum from the normal peripheral zone (a) shows the normal relationship between the choline and citrate peaks. The spectrum from the prostate cancer (b) shows increased choline and reduced citrate levels

Figure 6 Prostate carcinoma with extracapsular extension on the left: T_2 -weighted image, transaxial plane of section. Carcinoma (*) demonstrates low signal intensity. Prostate capsule (white solid arrows). There is a breach of the capsule (open white arrows) with direct cancer invasion to the neurovascular bundle. Normal neurovascular bundle on the right side (black and white arrowhead)

indicates tumor confined to the prostate gland. The low-signal-intensity tumor is seen within the peripheral zone, and while the lateral margin can bulge, the bulge is smooth in contour.^{21,22} With the endorectal coil, direct visualization of the prostate capsule increases the confidence level in the evaluation of TNM stage 2. In TNM stage 3 and Jewitt C disease, the findings of importance are extracapsular extension and seminal vesicle invasion.

MRI findings of extracapsular extension on endorectal coil include (a) bulge of the prostate gland with an irregular margin, (b) contour deformity with step-off or angulated margin, (c) breach of the capsule with direct tumor extension, (d) obliteration of the fat in the rectoprostatic angle, and (e) asymmetry, of the neurovascular bundles (Figure 6).^{12,21,22} Seminal vesicle invasion is diagnosed when there is (a) demonstration of contiguous low-signal-intensity tumor extension into and around the seminal vesicles, and/or (b) tumor extension along the ejaculatory duct resulting in nonvisualization of the ejaculatory duct, decreased signal intensity of seminal vesicles, and loss of seminal vesicle wall on T_2 -weighted images (Figure 7).

While transaxial planes of section are essential in the evaluation of extracapsular extension, the invasion of the seminal vesicles is facilitated by the evaluation of transaxial and coronal planes of section.^{12,23–25} In recently reported studies using the Jewitt classification and endorectal coil, the accuracy for extracapsular extension was 82% and accuracy for seminal vesicle invasion 97%.¹² These reports are in accordance with previously published results by Schnall et al.,²⁴ although they are higher than the latest publications by Chelsky et al.²⁵ In the evaluation of lymph node metastases, reports in the literature testify to the superiority of MRI over CT. However, none of the studies has sufficiently high numbers of positive nodes for

Figure 7 Prostate carcinoma with extracapsular and seminal vesicle extension: T_2 -weighted image, coronal plane of section. Prostate cancer (*) is seen at the base of the prostate gland on the right. Irregular outer margin indicates extracapsular invasion. There is also evidence of direct tumor invasion (white arrows) into the right seminal vesicle (SV)

statistically meaningful analysis. The accuracy of staging of cancer of the prostate depends on the type of coil used and appears to be most accurate when the combination of endorectal and surface multicoil system is used.^{11,19–26} Contrast-enhanced images do not contribute to either tumor detection or staging except in rare instances when they help in the detection of seminal vesicle invasion.⁴

3 SEMINAL VESICLES

3.1 Anatomy

The seminal vesicles are paired, androgen-dependent accessory sex glands. On T_1 -weighted images, normal seminal vesicles demonstrate homogeneous medium signal intensity similar to that of the adjacent pelvic muscle. On T_2 -weighted images, seminal vesicles demonstrate a grape-like configuration with the high-signal-intensity fluid differentiated from the low signal intensity of the inner convolutions and outer wall (Figure 1).²⁷ The size and the signal intensity of the seminal vesicles depends on patient's hormonal status and will decrease with patient's age, hormonal replacement therapy, radiation therapy, or severe alcoholism.²⁷ On contrast-enhanced T_1 -weighted images, the internal architecture of the seminal vesicles is depicted with the convolutions and wall demonstrating enhancement while the vesicular fluid remains of low signal intensity.^{4,6} Although great variation in the size of normal seminal vesicles can occur in adult men of the same age, there is a tendency for a decrease in size with advancing years. Seminal vesicles are usually symmetric in size, but asymmetry has been reported in up to 10% of patients.⁶

3.2 Pathology

3.2.1 Congenital Anomalies

Congenital anomalies of the seminal vesicles include the absence of the seminal vesicles and more commonly seminal vesicle cysts. In diagnosing the absence of seminal vesicles, T_1 -weighted transaxial images are most useful.²⁷ In the evaluation of seminal vesicle cysts, MRI provides precise anatomical localization but the signal intensity depends on its fluid composition.⁵ Blood is often present within the cyst with its signal intensity depending on the age of the hemorrhage.

3.2.2 Inflammatory Disease

Inflammation of the seminal vesicles is usually associated with epididymitis and the associated ascending spread of infection through the prostate gland. The MRI appearance varies with the stage of inflammation. Seminal vesicles are often enlarged in the acute stage and small in the chronic phase. Hemorrhage within the seminal vesicles is common in subacute infection.²⁷ Chronic inflammation results in small atrophic seminal vesicles often of lower than normal signal intensity on T_2 -weighted images.⁶

3.2.3 Tumors

The benign tumors of seminal vesicles (leiomyomas predominate) are more common than primary malignant neoplasms which are usually adenocarcinomas. The vast majority of malignant tumors of the seminal vesicles are secondary usually from prostate carcinoma, but extension from cancer of the bladder or rectum can be seen as well. The differentiation between benign and malignant tumors is usually based on the morphologic findings.²⁸ Benign tumors appear as smooth, well-margined masses while malignant invasion of the seminal

vesicles usually results in masses of low signal intensity and are irregular in configuration.²⁸ Loss of normal adjacent tissue planes also suggests secondary involvement of the seminal vesicles (Figure 7). Tumor extension into the seminal vesicles is best seen on T_2 -weighted images, in the sagittal and coronal planes.^{6,28}

4 PENIS/URETHRA

4.1 Anatomy

The penis is composed of three erectile bodies: the two lateral corpora cavernosa and the ventromedial corpus spongiosum (Figure 8).²⁹ Each of the three erectile bodies is enveloped by a fibrous sheath—the tunica albuginea. Buck's fascia—a common fibrous sheath—divides the penis into its dorsal compartment by enclosing the two corpora cavernosa and the ventral compartment by enclosing the corpus spongiosum. The male urethra extends from the bladder neck to the fossa navicularis in the glans penis. It is divided into the prostatic, membranous, and penile portions of the urethra. On T_1 -weighted images, the three erectile bodies demonstrate medium signal intensity, and they all increase in signal intensity on T_2 -weighted images (Figure 8). While the corpus spongiosum demonstrates homogeneous high signal intensity, the normal corpora cavernosa can be either homogeneous or heterogeneous in signal intensity depending on the blood volume within the erectile tissue.²⁹ The tunica albuginea and Buck's fascia appear as a low-signal-intensity stripe surrounding the corporeal bodies on T_2 -weighted images and provide excellent contrast with the high-signal-intensity corpora.²⁹ The use of contrast enhancement allows demonstration of the penile anatomy on T_1 -weighted images.⁶

Figure 8 Normal anatomy of the penis. (a) Transaxial and (b) coronal plane of section: T_2 -weighted images. Corpora cavernosa (cc), corpus spongiosum (cs), tunica albuginea (short arrows), and Buck's fascia (long black arrow)

4.2 Pathology

4.2.1 Congenital Anomalies

Epispadia, hypospadia, or duplication of the penis (penis diphallus) are the three groups of most commonly encountered congenital anomalies of the penis. The ability of MRI to delineate each of the corpora allows precise definition of the type of anomaly and provides depiction of associated anomalies involving the perineum and the remaining genitourinary tract.²⁹ The clinical indications, however, are rare, the most common being evaluation of penis diphallus.

4.2.2 Inflammatory Disease

Peyronie's disease is an inflammatory condition of unknown etiology characterized by the development of fibrous plaque involving the tunica albuginea and extending into the corpora cavernosa. On T_2 -weighted MR images, the lower-signal-intensity plaque can be depicted in contrast to the higher-signal-intensity corpora cavernosa.^{30,31} MRI is not the primary method for diagnosing this condition. MRI, however, can provide information about the location and size of the plaque as well as the degree of cavernosal involvement. Furthermore, MRI can differentiate between the acute and chronic form of Peyronie's disease, especially when contrast media are used.

4.2.3 Trauma

Penile trauma usually results from direct blunt injury to the erect penis causing fracture of the penis or rupture of the corpora cavernosa. On T_2 -weighted MR images, the diagnosis of penile fracture is based on the finding of interruption of the normal low-signal-intensity tunica albuginea. Peripenile hematoma is often detected.^{29,32}

MRI is valuable in the presurgical evaluation of urethral trauma (grade 3) associated with complex pelvic injury. Separation between the prostatic apex, membranous, and bulbous urethra can occur in superior anteroposterior or lateral direction. Misalignment of greater than 2 cm in the superior direction and greater than 1 cm in the lateral direction necessitates a different surgical approach (perineal versus suprapubic with removal of the symphysis pubis).^{33,34} MRI can greatly assist in planning the surgical approach but thin-section T_2 -weighted images in all three orthogonal planes are essential for the assessment of this complicated problem.³⁴

4.2.4 Tumors

Penile carcinoma accounts for only about 1% of all male cancers, and carcinoma of the male urethra is even more rare.³⁵ When cancers are located in the glans penis or in the penile shaft, the locoregional tumor extent can usually be determined by physical examination. However, when the tumor involves the root of the penis or bulbomembranous urethra, the clinical evaluation is limited and MRI has a role in local staging of disease.²⁹ On MRI, penile and urethral carcinomas are usually not distinguishable as most lesions requiring radiologic assessment are advanced and have spread to involve adjacent structures. The use of T_2 -weighted images demonstrates the tumor of different signal intensity (usually lower) as compared with the adjacent normal high-signal-intensity erectile bodies (Figure 9). MRI, however, is not specific for cancer detection and cannot be distinguished from inflammatory disease.^{6,29} This is es-

pecially true for smaller lesions of the urethra. However, MRI can be of great help in locoregional tumor staging, and in therapy planning—surgery versus radiation therapy.²⁹ Metastasis to the penis can also be well evaluated by MRI. Metastasis demonstrates diffuse low signal intensity infiltrating the erectile bodies on T_2 -weighted images. Differentiation between primary and metastatic lesions is not possible.²⁹

5 TESTIS

5.1 Anatomy

On T_1 -weighted images, the testis demonstrates intermediate signal intensity, similar to that of the corpora cavernosa or corpus spongiosum and lower than that of subcutaneous fat. On T_2 -weighted images, the testis demonstrates high signal intensity in contrast to the lower-signal-intensity tunica albuginea (a dense fibrous connective tissue capsule) covering the testis (Figure 10).³⁶ The mediastinum testis has signal characteristics similar to tunica albuginea and is seen as a low-signal-intensity stripe invaginating into the high-signal-intensity testicular parenchyma (Figure 10).³⁶ The parietal and visceral layers of the tunica vaginalis are often separated by a small amount of normal serous fluid. As in a hydrocele, this normal fluid surrounds the testis completely except for the posteromedial bare area. The signal intensity of the epididymis is similar to the testis on T_1 -weighted images and much lower than the testis on T_2 -weighted images.³⁶

5.2 Pathology

5.2.1 Undescended Testis

An undescended testis is defined as a testis located outside the scrotum. MR diagnosis of undescended testes relies on the finding of an elliptical mass demonstrated along the expected path of testicular descent.³⁷ However, it has recently been reported that dynamic gadolinium-enhanced MR angiography improves the detection of atrophic undescended testes by showing enhancement of the pampiniform plexus.³⁸ When the undescended testis is in the inguinal canal, it is usually oval in shape while the intraabdominal testis assumes a more rounded configuration. The large field of view and multiplanar image capability of MRI allows precise identification of the undescended testis as being either high scrotal, intracanalicular, or intraabdominal in location. When the intraabdominal testis is located close to the internal inguinal ring, it is easily depicted by MRI. However, high abdominal testis is difficult to demonstrate with MRI and CT is the procedure of choice. MR imaging allows differentiation between the undescended testis, gubernaculum, and lymph nodes.³⁷ Lymph nodes lie outside the expected descent of the testis. The differentiation between the gubernaculum and the testis relies on their respective differences in signal intensity. The gubernaculum characteristically demonstrates very low signal intensity on both T_1 - and T_2 -weighted images as its predominant histologic composition is fibrous tissue. The signal intensity of the testis varies depending on the degree of atrophy but is never as low as a fibrous cord.

Figure 9 Cancer of the penis. (a) Transaxial and (b) coronal plane of section: T_2 -weighted images. Tumor (T) is seen invading both corpora cavernosa (cc), spectrum corpora cavernosa as well as corpus spongiosum (cs). In the coronal plane of section, the zonal anatomy of the penis is not visualized, and there is demonstration of tumor extension through the tunica albuginea (small black arrows)

5.2.2 Testicular Tumors

Testicular tumor is the most common malignancy among men of 15 to 34 years of age although it accounts for only 1% of all cancers in males.³⁵ The majority (90–95%) of testicular tumors are malignant germ cell tumors. The homogeneous high signal intensity of the normal testicular tissue serves as an excellent background for the depiction of intratesticular pathology.^{36,39,40} On T_2 -weighted images, testicular tumors usually

demonstrate a lower signal intensity than the adjacent normal testicular tissue (Figure 11). Although MR imaging has a high sensitivity rate for the detection of testicular tumors, its findings are variable and are not specific for tumor histology. While on T_2 -weighted images testicular tumors are mostly hypointense to the testis, they may demonstrate a signal intensity similar or even higher than testicular tissue. Tumors can be homogeneous or heterogeneous in signal pattern. While seminomas are typically homogeneous and hypointense, the

Figure 10 Normal testis, transaxial plane of section: T_2 -weighted image. Testis (T) demonstrates homogeneous high signal intensity. Tunica albuginea (solid arrow) is seen as a low-signal-intensity stripe. Mediastinum testis (open arrows)

nonseminomatous tumors are often heterogeneous and exhibit various signal intensities.⁴⁰ However, exceptions to the rule can be encountered.³⁶ Furthermore, differentiation between primary and secondary testicular tumors is not possible, and the MR appearance of benign tumors is similar to testicular cancer.⁴¹

Testicular cysts can usually be differentiated from testicular tumors especially when contrast media are used. They appear

Figure 11 Seminoma of the left testis. Testicular tumor (*) demonstrates low signal intensity as compared with the adjacent remaining higher signal intensity testicular tissue. Normal right testis (T)

as sharper margined lesions with fluid signal intensity characteristics.³⁶

5.2.3 Inflammatory Disease

Acute epididymitis is the most common inflammatory lesion in the scrotum. In acute epididymitis, the epididymis is enlarged and demonstrates heterogeneous and often higher signal intensity than normal. Hemorrhage may complicate acute epididymitis producing signal intensity commensurate with its age. Reactive hydrocele is often present. In chronic epididymitis, the signal intensity of the epididymis is reduced, a finding best appreciated on T_2 -weighted images.³⁹ Associated orchitis, when present, appears as a homogeneous or heterogeneous hypointense lesion within the normal sized or enlarged testis. The signal intensity change is most commonly present in the mediastinum region. Fibrotic thickening of the tunica albuginea can occur following epididymitis, and the thickening may sometimes be difficult to differentiate from small testicular cancer, thus the term 'pseudotumor of the tunica albuginea' has been introduced.⁴²

5.2.4 Spermatic Cord Torsion

Torsion is considered a surgical emergency since delaying intervention may result in irreversible damage to the testis. MRI plays no role and is not a primary imaging modality in diagnosing testicular torsion. Reports on MRI findings in acute torsion in humans are sporadic and not well documented. The testis may be normal or enlarged and of heterogeneous signal intensity. With testicular torsion, the spermatic cord can enlarge, exhibiting a high signal intensity due to edema. A twisted cord can be seen as multiple low-intensity curvilinear structures rotating in a 'whirlpool' pattern which is best seen in a plane perpendicular to its axis.⁴³ Torsion of the testicular or epididymal appendices can be identified with MRI by their typical location and the signal characteristics of hemorrhage.⁴³

5.2.5 Fluid Collection and Benign Scrotal Masses

Fluid collections whether hydrocele, hematocele, or pyocele all indicate abnormal fluid located between the parietal and visceral layers of the tunica vaginalis. The signal of hydrocele is typical for fluid (low signal intensity on T_1 -weighted image and high intensity on T_2 -weighted image).^{36,39} The signal intensity of hematocele varies with the age of the hemorrhagic fluid, and the proteinaceous component of pyocele usually makes the fluid signal intensity on T_1 -weighted images higher than that of hydrocele. Spermatocele is a retention cyst of small tubules which connect the rete testis to the head of epididymis. On MRI scan, the diagnosis of spermatocele can be made by its typical location (usually in the head of the epididymis) and its cystic nature.⁶

In scrotal pathology, MRI serves as a problem-solving modality when ultrasound findings are equivocal, technically inadequate, or there is a discrepancy between the physical examination and ultrasound findings. Recent studies have shown that when ultrasound and physical examination of the scrotum are inconclusive, MRI can improve patient management and reduce treatment costs.³⁷⁻⁴⁶

MRI of the Female Pelvis

Robert C. Smith, Michael J. Varanelli, Leslie M. Scoutt, and Shirley McCarthy

Yale University School of Medicine, New Haven, CT, USA

1 INTRODUCTION

The article will describe the clinical applications and technical considerations of MRI of the female pelvis. Due to its improved tissue contrast capability (compared with computerized tomography and ultrasound), MRI is the technique of choice for depicting normal uterine and cervical anatomy as well as a variety of benign and malignant conditions affecting these structures. MRI is also capable of delineating a number of nongynecological abnormalities of the pelvis.

Recent technical advances have dramatically improved the resolution that can be obtained when imaging the female pelvis. At the same time, these technical improvements have greatly reduced the imaging time. Both of these factors should improve the accuracy of MRI not only for detecting abnormalities but in the staging of gynecological malignancies. Cost-benefit analyses have shown MRI of the female pelvis to be cost-effective.

2 MRI TECHNIQUE

Imaging of the female pelvis requires both T_1 - and T_2 -weighted images.¹ T_1 -weighted images are useful for lymph node detection and to characterize regions which contain blood products and/or fat. T_2 -weighted images are necessary to depict the internal anatomy of the gynecological organs, characterize masses and other abnormalities, and determine the origin of a mass as uterine or ovarian.

T_1 -weighted images are typically acquired in the axial plane from the level of the aortic bifurcation through the pubic symphysis. The TR (repetition time) used is between 500 and 600 ms, and the minimum possible TE (echo time) is used (usually 10–15 ms). Superior and inferior saturation pulses are routinely used to diminish the intravascular signal and therefore help decrease pulsation artifacts and distinguish lymph nodes from vascular structures. In some cases, use of a longer TE (up to 20 ms) will help diminish intravascular signal. Respiratory compensation is always utilized to diminish ghost artifacts from the high-signal subcutaneous fat.²

Other typical parameters would include a field of view (FOV) of 24–30 cm, section thickness of 5 mm, intersection spacing of 2.0–2.5 mm, a frequency matrix size of 256, a phase matrix size of 128 or 192, and one or two signal averages. If there is a large amount of bowel within the pelvis, glucagon can be administered to help diminish artifacts from bowel peristalsis. In the majority of cases, glucagon is not necessary.

T_2 -weighted images should be acquired through the uterus and ovaries in at least two orthogonal planes. The main purpose of sagittal images is to depict the uterine and cervical

zonal anatomy. Depending upon the orientation of the uterus, the axial or coronal plane can be chosen to image the uterus in a plane perpendicular to its long axis. Both the axial and coronal planes will usually depict the ovaries to good advantage. The T_2 -weighted images should be acquired using fast spin echo (FSE) or turbo spin echo (TSE) pulse sequences.^{3,4} Using these, high-resolution T_2 -weighted images can be acquired through the entire pelvis in less than 5 min.

3 FSE IMAGING

When FSE T_2 -weighted images are acquired in a body coil, typical imaging parameters would include a TR of 4500–6000 ms, a TE of 100–130 ms, a 5 mm section thickness, a 2.0–2.5 mm intersection spacing, a minimum phase matrix size of 192, a FOV of 24–28 cm, and two to four signal averages. If a small FOV is used with a phase matrix size of 256, this usually necessitates use of four signal averages to maintain the signal-to-noise ratio (S/N) at an acceptable level.

In addition to the above parameters, the echo train length (ETL) and the echo spacing (ESP) must also be specified when using FSE sequences. With conventional spin echo sequences, a single phase-encoding step is acquired during each TR interval. Even if multiple echoes are measured (as with proton density and T_2 -weighted images), each is acquired with the same phase-encoding step. The multiple echoes are used to generate multiple images (of different TE) at each imaging location. In order to reconstruct an image, the number of phase-encoding steps must equal the size of the phase matrix. It is this fact which makes the imaging time of conventional spin echo sequences so long.

FSE sequences acquire multiple phase-encoding steps during each TR interval. This is achieved by applying multiple 180° pulses after each 90° pulse and separately phase encoding the resulting spin echoes. The ETL is equal to the number of separately phase-encoded echoes acquired following each 90° pulse. The maximum value of the ETL is usually 16 or 32. Recent development of 'single-shot' techniques using a half-Fourier reconstruction allows an ETL of 128 or 192 and acquisition of each image in about 1 s. Once all of the separately phase-encoded echoes have been acquired in one section, data are then acquired in the next section. The spacing between the separate phase-encoded echoes is the ESP. The minimum value of ESP is usually 6–8 ms and depends on the bandwidth. In almost all circumstances the minimum value of ESP should be used.

Regardless of the imaging technique, each phase-encoding step uses a different strength phase-encoding gradient. Echoes acquired with the weak phase-encoding gradients provide most of the signal (and hence contrast) of an image, and echoes acquired with the strong phase-encoding gradients provide most of the spatial resolution of an image. With the fast spin echo technique, multiple separately phase-encoded echoes are used to generate a single image at each location. The overall contrast of such images is determined by the echo times at which the weak phase-encoding steps are acquired.^{5–7} If the weak phase-encoding steps are used for the early echoes, the image will appear as either proton density or T_1 weighted (depending on the TR). If the weak phase-encoding steps are used for the late echoes, the image will appear as T_2 weighted.

For this reason, the echo time of an FSE image is usually referred to as an effective TE . When the user selects an effective TE , the phase-encoding steps are assigned to the appropriate echoes of each multiecho train following each 90° pulse. Severe artifacts can result from this technique. Late echoes have diminished signal due to T_2 decay. If the strong phase-encoding gradients are applied to the late echoes (as with proton density- and T_1 -weighted FSE images), there may be no useful signal left. Since the strong phase-encoding gradients provide the spatial resolution of an image, without these phase-encoding steps there will be a loss of spatial resolution. This is manifest as image blurring, which can be severe.

Image blurring is minimized by using a shorter ETL (usually 4 or 6) when acquiring proton density- or T_1 -weighted FSE images. T_2 -weighted FSE images never suffer from this blurring effect since the strong phase-encoding gradients are always applied to the early echoes. Early echoes suffer minimal signal loss due to T_2 decay. Therefore, T_2 -weighted FSE images can usually be acquired with the maximum possible value of ETL.

The imaging time of a conventional spin echo sequence is given by $TR \times (\text{phase matrix size}) \times (\text{number of signal averages})$. The imaging time of an FSE sequence is this same product divided by ETL. However, when using FSE sequences, the number of sections that can be acquired for a given TR will be diminished. This results from the fact that many more echoes must be measured in each section before moving on to the next section. Depending on the choice of ETL, this will usually necessitate the use of a longer TR with FSE sequences.

The shorter the ETL, the more sections that can be acquired per TR interval. For example, using a TR of 3000 and an ETL of 8 will give approximately the same number of sections as using a TR of 6000 and an ETL of 16. The imaging times will be the same. The advantage of using a longer TR is that it gives a true T_2 -weighted image. The trade-off is that use of a shorter ETL will improve the S/N since fewer late echoes are acquired. One must always keep in mind that the maximum value of TE that can be achieved is equal to $ETL \times ESP$. Therefore, use of a shorter ETL will limit the maximal value of TE .

When imaging the pelvis in a body coil with FSE sequences, one can use either an ETL of 8 (with a TR of 3000–4000 ms) or an ETL of 16 (with a TR of 6000–8000 ms). It is recommended that a 192 or 256 phase matrix is used. There is usually a significant relative image degradation when a 128 phase matrix size is used with FSE images.

4 MULTICOIL IMAGING

When imaging with a single surface coil there is a marked improvement in the S/N, but the FOV that can be achieved is severely limited (roughly of the order of the diameter of the coil). In addition, the relative phase of the signal will depend upon the orientation of the surface coil within the magnet. If multiple surface coils are used together and their signals are combined into a circuit, there can be signal loss due to phase differences between the two signals. This can be minimized by careful orientation of the coils.

A multicoil (also called a phased-array coil) consists of multiple surface coils which act independently in a receive-only

mode. Each separate coil of the multicoil inputs its signal into separate receiver channels. The signals from the individual coils are then used to reconstruct an individual image for each coil. These separate images are then recombined into a single composite image. In this case the relative phases of the individual signals is irrelevant, as the signals are only combined after magnitude reconstruction. By using a multicoil one gets the improved S/N of a surface coil, and the FOV that can be achieved is comparable to a body coil.^{8–10} The only disadvantage of a multicoil is that four separate receiver channels must be used, which is expensive. All pelvic imaging should now be performed using a multicoil and FSE pulse sequences.

When using a multicoil, the signal from subcutaneous fat immediately adjacent to the coils will be markedly increased and can result in significant ghost artifacts. This can be eliminated by the placement of saturation pulses (within the field of view) through the subcutaneous fat both anteriorly and posteriorly.

5 NORMAL ANATOMY

On T_1 -weighted images the uterus has a homogeneous low signal intensity. The appearance is similar to that of the uterus on computed tomography images, as no internal architecture is visible. On T_2 -weighted images, a zonal architecture of the uterus is readily identified. The appearance of the zonal anatomy depends upon whether the patient is pre- or postmenopausal and the phase of the menstrual cycle.^{11–13}

In virtually all premenopausal patients, three distinct zones of signal intensity can be seen in the uterine corpus (Figure 1).¹² An inner zone of high signal corresponds to the endometrium. An adjacent zone of low signal intensity corresponds to the so-called junctional zone. Histological studies have shown this zone to represent an inner layer of myometrium which has an increased nuclear area.¹⁴ The remainder of the myometrium has intermediate signal intensity but can be quite variable, depending on the hormonal milieu of the patient.

Previous studies have shown that the inner bright zone progressively increases in thickness during the menstrual cycle with a peak thickness occurring late in the secretory phase. The thickness may vary from 4 mm early in the proliferative phase to 13 mm late in the secretory phase. The junctional zone shows no significant change in thickness during the menstrual cycle. In patients taking oral contraceptives (combined estrogen and progestin), endometrial thickness is markedly reduced after several months. In addition, the outer myometrium of these patients shows relatively increased signal intensity compared with those not using oral contraceptives.

Ultrasound studies have been performed in an attempt to determine an approximate upper limit of normal for endometrial stripe thickness in postmenopausal patients.^{15,16} Regardless of hormonal replacement therapy, an upper limit of 8 mm has been suggested. No similar large series have as yet been performed with MRI. However, a comparative study of ultrasound and MRI has shown that the MRI measurement of endometrial thickness is almost always smaller than the corresponding ultrasound measurement.¹⁷

The cervix also has a unique zonal anatomy on T_2 -weighted MRI (Figure 1). Four distinct zones of signal intensity have been described:^{4,18} a thin inner bright zone which corresponds

Figure 1 Sagittal FSE multicoll image demonstrating the zonal anatomy of the uterus. The endometrium is the central bright stripe (curved arrow). Note the surrounding low-signal junctional zone and intermediate-signal outer myometrium. Within the cervix, the central high signal represents the canal (straight arrow) and contained mucus. The next layer is the intermediate-intensity signal of the cervical mucosa which is surrounded by the low-intensity signal of the fibrous stroma. Finally, the outer cervical stroma has an intermediate signal intensity and is continuous with the myometrium

to the endocervical canal; an adjacent thin zone of intermediate signal intensity corresponding to the cervical mucosa; a thicker zone of very low signal intensity thought to correspond to the predominantly fibrous portion of the wall of the cervix; and an outer zone which is continuous with the myometrium and is isointense with the myometrial signal.

Previous studies have shown little variation in the appearance of the cervix during the course of the menstrual cycle.¹³ In addition, there is no apparent difference in the appearance of cervical zonal anatomy between premenopausal and postmenopausal women, or between those using and not using oral contraceptives.

The normal MRI appearance of the vagina is less complex. The vaginal wall typically shows low signal intensity, and the vaginal canal typically appears as a bright stripe of high signal intensity corresponding to vaginal secretions. The vagina is surrounded by the high signal intensity perivaginal venous plexus.

The ovaries appear homogeneously hypointense on T_1 -weighted images. Follicles appear as small, round, homogeneous areas of high signal intensity on T_2 -weighted images. The ovarian stroma is of low to intermediate signal intensity on T_2 -weighted images. With high-resolution imaging, it is almost always possible to identify the ovaries in premenopausal patients, and most of the time in postmenopausal patients.

6 BENIGN DISEASES OF THE UTERUS AND CERVIX

The most common benign mass of the uterus is the leiomyoma, also commonly referred to as a fibroid. These masses are sharply circumscribed, usually spherical in shape, and typically have low signal intensity on all pulse sequences. When fibroids become large, they can undergo degeneration, which is usually manifest as central increased signal intensity on T_2 -weighted images.

MRI is uniquely able to determine the intrauterine location of these masses. Fibroids are usually described as being submucosal, intramural, or subserosal in location. Submucosal fibroids are commonly associated with abnormal menstrual bleeding (Figure 2). Intramural fibroids are not usually associated with abnormal menstrual bleeding but are a common cause of uterine enlargement (Figure 3). Subserosal fibroids can be on a stalk and therefore can undergo torsion. Subserosal fibroids can also be confused with an adnexal mass on physical examination and on other imaging modalities.

When fibroids cause significant clinical symptoms and surgery is contemplated, the surgical approach is dependent upon the precise location of the fibroids. Some submucosal fibroids can be removed hysteroscopically. Intramural and subserosal fibroids can only be removed using a transabdominal approach. In addition to their location, another important surgical consideration is the size and increased vascularity of these lesions. Hormonal therapy is sometimes used to decrease their size and vascularity prior to possible surgery. MRI can be used to follow precisely the size and vascularity during such therapy.

Adenomyosis is defined as the presence of endometrial tissue within the myometrium. This tissue is usually not functional. The appearance of adenomyosis on MRI scans is rather characteristic.¹⁹ It appears as focal or diffuse ill-defined thickening of the junctional zone (Figure 4). It has low signal

Figure 2 Sagittal FSE multicoll image demonstrating a submucosal fibroid (arrow)

Figure 3 Coronal FSE multicoil image demonstrating a large intramural fibroid (arrow) displacing the endometrial stripe

intensity on T_2 -weighted images, being isointense with the junctional zone. In some cases, adenomyosis can appear as small foci of high signal intensity within the myometrium on T_2 -weighted images. Adenomyosis can result in uterine enlargement and abnormal menstrual bleeding. It is therefore important to differentiate this condition from fibroids. MRI is particularly useful in making this distinction.

Figure 4 Sagittal FSE multicoil image demonstrating adenomyosis (arrow). Note the diffuse irregular thickening of the junctional zone with tiny areas of hyperintensity characteristic of the disease

Figure 5 Axial FSE multicoil image demonstrating diffuse thickening of the endometrium (arrow) consistent with endometrial hyperplasia

Endometrial hyperplasia is thought to represent a physiological response of the endometrium to unopposed estrogenic stimulation. Some forms of endometrial hyperplasia are known to be precursors of endometrial carcinoma. On MRI, endometrial hyperplasia appears as thickening of the high-signal endometrium on T_2 -weighted images (Figure 5).¹ However, MRI cannot distinguish between hyperplasia and early carcinoma.

Endometrial polyps can be sessile or pedunculated masses projecting into the endometrial cavity. They can be associated with abnormal uterine bleeding. However, endometrial carcinoma can sometimes have a polypoid configuration and cannot be reliably distinguished from simple polyps. On T_2 -weighted images, polyps may appear as intermediate-signal masses (with respect to the low-signal junctional zone and the high-signal endometrium) but can also be isointense with the endometrium. Gadolinium-enhanced T_1 -weighted images may be useful in detecting endometrial polyps. The enhancing polyp can be outlined by nonenhancing fluid within the endometrial cavity.

Pedunculated submucosal fibroids can also appear as polypoid filling defects within the endometrial cavity on MRI. Their signal intensity is usually significantly lower than that of endometrial polyps, which helps in their distinction.

The two most common uterine anomalies that need to be differentiated are the septate uterus and the bicornuate uterus.²⁰ In the septate uterus, the external contour of the uterus is normal (Figure 6). In the bicornuate uterus (Figure 7), there are two separate horns of the endometrial cavity, and the external contour of the uterus is significantly indented at the fundus (as there is no uterine tissue in the space between the two horns).

By imaging through the fundus along the long axis of the uterus, these two entities can be reliably distinguished. The signal characteristics of the septum may reflect myometrial or fibrous tissue, and hence signal behavior is not useful in classi-

Figure 6 Axial FSE multicoil image of a septate uterus. The contour of the uterine fundus is normal, and a large myometrial septum (arrow) is present

Figure 7 Axial FSE multicoil image of a bicornuate uterus. The contour of the uterine fundus is abnormal, with a large indentation separating the two endometrial cavities. There is a large low-signal intensity leiomyoma in the right horn

fying anomalies. The septate uterus is more commonly associated with infertility, and can be treated surgically through a hysteroscopic approach.

There are only a few benign lesions of the cervix commonly seen on MRI. Nabothian cysts represent dilated cervical glands usually seen following inflammation. These are very commonly visualized on MRI as homogeneous, round, sharply circumscribed areas of very high signal intensity on T_2 -weighted images. Rarely, fibroids can be seen originating from the cervix. These are otherwise identical to those originating within the uterus.

7 MALIGNANT DISEASE OF THE UTERUS

Endometrial carcinoma is the most common invasive malignancy of the female genital tract. Unlike cervical carcinoma, there is not a well documented progression from precursor lesions to invasive carcinoma. Known risk factors for the development of endometrial carcinoma include obesity, nulliparity, late menopause, diabetes mellitus, hypertension, polycystic ovarian syndrome, estrogen-producing tumors, and unopposed exogenous estrogen supplementation.

MRI has been shown to be useful in evaluating patients with known endometrial carcinoma. The vast majority of patients with endometrial carcinoma (up to 75%) will have stage I disease at the time of diagnosis. Tumor grade and depth of myometrial invasion are the two important prognostic factors which can affect therapy in these patients.^{21–23} Tumor grade will be known based upon histological findings. However, depth of myometrial invasion can only be determined preoperatively with the use of imaging studies.

On T_1 -weighted images, most endometrial carcinomas are isointense with the uterus unless they contain hemorrhagic areas. On T_2 -weighted images, most endometrial carcinomas (large enough to be detected as distinct masses) have a signal intensity intermediate between normal endometrium (higher signal intensity) and normal myometrium (lower signal intensity).

Multiple studies have been performed evaluating the ability of MRI to depict accurately the depth of myometrial invasion.^{24–31} Using T_2 -weighted images and/or gadolinium-enhanced T_1 -weighted images, these studies have shown an accuracy of 75–95% in distinguishing superficial from deep myometrial invasion (Figure 8). More importantly, these studies have shown that an intact junctional zone has a 100%

Figure 8 Axial multicoil image acquired following gadolinium administration demonstrates a large tumor extending beyond the uterus (arrow)

negative predictive value (NPV) in excluding myometrial invasion, and that segmental disruption of an otherwise intact junctional zone has a 100% positive predictive value (PPV) in detecting at least superficial myometrial invasion.

Unfortunately, most patients with endometrial carcinoma are postmenopausal, and uterine zonal anatomy may not be as conspicuous as that seen in premenopausal patients. Thus, these data are based on a small number of patients. In addition, patients with large intraluminal polypoid tumors can have significant expansion of the endometrial cavity with resultant distortion of zonal anatomy. Accurate assessment of myometrial invasion can be impossible in such cases.³²

In patients without visible zonal anatomy, the presence of myometrial invasion must be presumed, based upon the appearance of the endometrial/myometrial interface. If this interface is irregular, invasion is presumed to be present, and if this interface is smooth, invasion is presumed to be absent. However, these findings do not have a high PPV or NPV, and this limits their usefulness.

All patients with clinically suspected stage I endometrial carcinoma must have evaluation of the cervix for possible tumor involvement. Endocervical curettage can be unreliable in this assessment. A few studies indicate an NPV of nearly 100% for MRI detection of cervical involvement.^{25,29} The positive data regarding MRI evaluation of cervical involvement in patients with endometrial carcinoma are more limited. This is because only a small number of patients will have cervical involvement, since the vast majority have stage I disease at the time of presentation. In addition, some patients may have distention of the cervical canal by clot or debris, which can give a false-positive diagnosis of cervical involvement.

Uterine sarcomas are relatively rare tumors accounting for only 3–5% of all uterine cancers.³³ The three most common histological variants are malignant müllerian mixed tumor (MMMT), leiomyosarcoma (LMS), and endometrial stromal sarcoma (ESS). MMMT and LMS each account for about 40% of all uterine sarcomas, while ESS accounts for 10–15%. The staging system for uterine sarcomas is the same as that used for endometrial carcinoma.

The incidence of sarcomatous change in preexisting uterine leiomyomas is reported to be between 0.1 and 0.8%.³³ A small percentage (4%) of these patients will have a history of prior pelvic radiotherapy. The presenting clinical symptoms include vaginal bleeding, pelvic pain, and pelvic mass. The diagnosis should be suspected if rapid uterine growth occurs, especially in a postmenopausal patient.

MMMTs are histologically composed of a mixture of sarcoma and carcinoma. Almost all of these tumors occur after menopause. A history of prior pelvic radiotherapy can be elicited in up to 35% of cases.³³ Postmenopausal bleeding is the most common presentation. The tumor usually grows as a large polypoid mass with areas of necrosis and hemorrhage. It spreads in a manner identical to endometrial carcinoma but tends to be more aggressive with significant myometrial invasion in almost all cases.

Endometrial stromal tumors are rare tumors composed of cells resembling normal endometrial stroma. They can be divided into three types based upon mitotic activity, vascular invasion, and prognosis.³³ The endometrial stromal nodule is a benign lesion confined to the uterus. Endolymphatic stromal myosis infiltrates the myometrium, may extend beyond the

uterus, and can metastasize. ESS, the third type of stromal tumor, is differentiated from stromal myosis mainly on the basis of mitotic activity and its much more aggressive course. Stromal tumors usually occur in perimenopausal patients. The MRI appearance of LMS and endometrial stromal tumors is not well known. The MRI findings in a series of seven patients with surgically proven MMMT showed this tumor to have an appearance similar to endometrial carcinoma.³⁴ The only feature that might suggest the diagnosis is that these tumors are usually very large and show deep myometrial invasion. However, when detected early, these tumors have an appearance identical to early endometrial carcinoma.

Trophoblastic tissue can give rise to a variety of tumors.³⁵ Complete hydatidiform mole, partial hydatidiform mole, invasive mole, and choriocarcinoma arise from villous trophoblastic tissue, while placental site trophoblastic tumor arises from non-villous trophoblastic tissue.

Complete hydatidiform mole has been shown to be the result of a purely paternal conceptus. This genetic abnormality results in trophoblastic differentiation and proliferation without development of an embryo. Partial hydatidiform mole is seen almost exclusively in triploid conceptuses, with two paternal chromosomal complements and one maternal chromosomal complement. Often a malformed fetus is found in association with a partial mole. The partial mole itself usually arises from only a portion (or part) of the placenta. Clinical presentation of these entities can be abnormal uterine enlargement, vaginal bleeding, elevated human chorionic gonadotropin levels, or the absence of fetal heart sounds.

Invasive moles are thought to develop in previously existing complete moles. They are most commonly seen in the early months following evacuation of a complete hydatidiform mole. The hallmark of this entity is myometrial invasion. Choriocarcinoma is a malignant neoplasm which most commonly occurs after a molar pregnancy (sometimes remotely) but can be seen after a normal pregnancy, abortion, ectopic pregnancy, and possibly *de novo*.

Placental site trophoblastic tumor arises from the nonvillous trophoblast which infiltrates the placental site in normal pregnancy. It is considered an atypical form of choriocarcinoma. The importance of recognizing this tumor type pathologically lies in its less aggressive behavior compared with choriocarcinoma. This behavior makes this tumor amenable to surgery but often resistant to chemotherapy.

There are few data regarding the role of MRI in the evaluation and management of patients with trophoblastic tumors.^{36,37} MRI is usually performed in patients with a known diagnosis of persistent mole following therapy or patients developing invasive mole or choriocarcinoma. A few studies have shown that prior to therapy most tumors show heterogeneous signal intensity on T_2 -weighted images and distort or obliterate the normal zonal anatomy. These tumors only rarely appear as endometrial masses. Many tumors show markedly increased vascularity as evidenced by visualization of tortuous, dilated vessels within the tumor and/or the adjacent myometrium.

Previous studies have also shown that in patients responding to chemotherapy there was a progressive decrease in uterine size, tumor size, tumor vascularity, and a progressive improvement in visualization of normal zonal anatomy. All patients completely responding to therapy will show normal uterine

size, normal zonal anatomy and no evidence of tumor following completion of chemotherapy.

8 MALIGNANT DISEASE OF THE CERVIX

Invasive cervical cancer is thought to develop over time from noninvasive precursor lesions.³⁸ These precursor lesions are referred to as cervical intraepithelial neoplasia (CIN). CIN is divided pathologically into three grades: CIN 1 (minor dysplasia), CIN 2 (moderate dysplasia), and CIN 3 (severe dysplasia). CIN 3 is synonymous with carcinoma-in-situ. Available evidence indicates that up to 40% of CIN 3 lesions and a lesser proportion of CIN 1 and CIN 2 lesions would progress to invasive cancer if untreated. Imaging studies play no role in the detection of cervical carcinoma or its precursor lesions.

On T_1 -weighted images, cervical carcinoma is of intermediate signal intensity and usually isointense with the uterine corpus and cervix. On T_2 -weighted images, cervical carcinoma is usually of intermediate signal intensity relative to the low-signal fibrous cervical stroma and high-signal cervical and endometrial canals. It is the sharp contrast with the fibrous stroma that makes T_2 -weighted imaging so crucial in depicting the tumor and its depth of invasion.

Most patients with CIN or microinvasion will have a normal appearance on MRI.³⁹ However, some patients with early invasive disease can also have a normal appearance on MRI. Prior studies have shown that the detection of a macroscopic lesion on MRI had a 100% PPV in determining the presence of at least invasive disease. A normal appearance on MRI has a less than 100% NPV in excluding the presence of invasive disease. Thus, a normal MRI requires further investigation to exclude early invasive disease. It is important to note that there are few studies in the literature evaluating this point, and few studies have been performed with high-resolution imaging.

The therapy of cervical carcinoma is dependent upon the stage of the disease at the time of diagnosis. The most crucial determination is the presence or absence of tumor invasion into the parametrium. Patients without parametrial invasion will usually be treated surgically. The presence of parametrial invasion precludes surgical therapy.

A number of MRI studies have shown that the finding of a completely intact ring of low-signal intensity cervical stroma has a 100% NPV in excluding parametrial invasion (Figure 9).³⁹⁻⁴² Unfortunately, focal areas of disruption of the stromal ring or full-thickness involvement of the fibrous stroma by tumor have a significantly lower than 100% PPV in determining parametrial invasion.

The ability of MR imaging to accurately determine vaginal, pelvic sidewall, bladder, and rectal involvement in patients with cervical carcinoma has been evaluated in only a limited number of studies. The NPV of MR in excluding involvement of these structures is probably close to 100%. The PPV is difficult to assess because of the small number of positive cases.

There is little if any role for gadolinium-enhanced MR imaging in the staging of cervical carcinoma.^{24,27,43} Several studies have indicated that gadolinium-enhanced images consistently overestimate the depth of cervical invasion. In addition, there is overestimation of involvement of the parametrium, bladder, and vagina with gadolinium-enhanced images.

Figure 9 Coronal FSE multicoll image demonstrating a large tumor in the right cervix. The thin rim of intact fibrous stroma (curved arrows) indicates that parametrial invasion is absent

9 BENIGN DISEASE OF THE OVARIES

In premenopausal patients the normal ovaries almost always contain multiple small follicles (Figure 10). These appear as round, unilocular, sharply circumscribed high-signal areas on T_2 -weighted images. They are usually less than 1.0 cm across but can attain a size of 2.5 cm and still be considered normal follicles. A corpus luteum cyst or follicular cyst can have an identical appearance to normal follicles other than their slightly larger size. They can sometimes contain hemorrhage, which will be seen as a high signal on T_1 -weighted images. Theca lutein cysts can be seen in association with excessive levels of hCG, generally associated with trophoblastic disease. These cysts are usually multilocular, bilateral, and very large.

It is well known that even postmenopausal patients may have simple cysts within their ovaries.⁴⁴ Studies in the ultrasound literature have shown that if a cyst is simple, less than 3.0 cm in size, and shows no abnormal flow on Doppler evaluation, it is most probably benign. There are no similar studies in the MRI literature.

An infrequently seen benign disorder of the ovaries is polycystic ovarian disease. This is thought to result from unopposed estrogenic stimulation and chronic anovulation. This disorder is commonly associated with obesity, hirsutism, and oligomenorrhea. On MRI, the ovaries in these patients usually appear mildly enlarged, and contain multiple small cysts in the periphery with an abundant central stroma.

A common cystic lesion of the adnexal region is the paratubal cyst. These cysts develop from wolffian duct remnants within the broad ligament, separate from the ovary. These are almost always benign in nature. Their appearance is indistinguishable from simple ovarian cysts, other than their

Figure 10 Axial FSE multicoil image demonstrating multiple follicles within the ovaries. The appearance suggests polycystic ovarian disease

extraovarian origin. It is this latter point that is key to their diagnosis. Although there is a paucity of published data, paratubal cysts usually displace an otherwise normal appearing ovary and therefore appear as a separate structure.⁴⁵

Another cystic adnexal lesion is the Gartner's duct cyst.⁴⁵ This develops in a remnant of the müllerian duct. Their signal

Figure 11 Sagittal conventional spin echo image of a mucinous cystadenoma (curved arrow). Note the thin septations and lack of solid elements. The signal behavior of the mass is identical to urine in the bladder (straight arrow) on all sequences

characteristics are identical to other cystic lesions. They can be diagnosed by their paravaginal location (separate from the ovaries) and usually tubular configuration. They are usually well demonstrated on high-resolution MRI. These patients commonly present with dyspareunia.

Benign epithelial tumors of the ovary include serous and mucinous cystadenomas (Figure 11). The appearance of these tumors at MR imaging is variable, and can be indistinguishable from their malignant counterparts. Benign cystadenomas can appear as simple cystic intraovarian masses. The presence of internal septations, solid components, or papillary projections makes malignancy more likely. Intravenous gadolinium can sometimes be helpful in detecting solid components, papillary projections or even septations.⁴⁶

Ovarian fibromas, fibrothecomas, and Brenner tumors are solid ovarian masses that can contain fibrous tissue, and, therefore, may show diffuse or focal areas of low signal intensity on all pulse sequences. Fibromas are typically extremely low signal intensity, while fibrothecomas typically contain multiple high-signal foci. One must be careful to distinguish these masses from pedunculated subserosal fibroids. The only way to do so definitively is to identify them as intraovarian.

Two ovarian lesions which can occasionally be difficult to distinguish are the ovarian dermoid and an ovarian endometrioma.⁴⁷ The dermoid tumor is the most common form of benign teratoma, and can be definitively characterized by its fat content. Endometriosis is a disease characterized by rests of normal functional endometrium in abnormal locations. The most common location of endometriosis is the ovary. This can occur as a large mass, referred to as an endometrioma, which can be characterized by its blood content.

On MRI, a dermoid and an endometrioma can have identical signal characteristics on both T_1 - and T_2 -weighted images. The most definitive way to distinguish these lesions is by using sequences which selectively suppress the signal from fat- or water-containing structures.⁴⁷ The fat in dermoids is of high signal on T_1 -weighted images obtained with and without water suppression, and is of low signal on T_1 -weighted images obtained with fat suppression (Figure 12). Endometriomas appear as a high signal on T_1 -weighted images obtained with and without fat suppression, and appear as a low signal on T_1 -weighted images obtained with water suppression.

Unfortunately, endometriomas are indistinguishable from other hemorrhagic cysts. Multiple such cysts make the diagnosis of endometriosis more likely (Figure 13). Sometimes hemosiderin can be visualized within and on the surface of the ovaries. Hemosiderin appears as tiny foci of low signal, most conspicuous on T_2 -weighted images. MRI is insensitive in detecting small implants of endometriosis involving bowel, the bladder, or other peritoneal surfaces.

10 MALIGNANT DISEASE OF THE OVARIES

The most common malignant neoplasms of the ovary are of epithelial origin, particularly serous and mucinous cystadenocarcinomas (Figure 14). These tumors often appear primarily cystic in nature. On MRI, the cystic portions will appear as very high-signal areas on T_2 -weighted images. They also, however, commonly contain internal septations and solid elements.

Figure 12 Complex dermoid containing both fluid and fat elements. Note that the fat (arrow) is isointense with pelvic fat on the (a) T_1 -weighted and (b) T_2 -weighted images. On the (c) water suppression and (d) fat suppression images, the fat (arrows) suppresses on the latter sequence

The solid components are of lower signal on the T_2 -weighted images, and often show enhancement following intravenous administration of gadolinium.⁴⁶ However, these tumors can sometimes appear indistinguishable from simple cysts. In general, even when purely cystic in appearance, these masses will be larger in size than other simple benign cysts. A variety of other malignant neoplasms that are primarily solid or mixed can involve the ovaries.

Ovarian malignancies usually spread from the surface of the ovaries into the peritoneal cavity. Most commonly, metastases involve the omentum, mesentery, and peritoneal surface of solid viscera. Due to artifacts from the bowel, MRI is not as

sensitive as computerized tomography in detecting these metastases. Intravenous gadolinium is essential if one attempts to detect these metastases on MRI.

Pediatric Body MRI

Rosalind B. Dietrich and Gerald M. Roth

University of California, Irvine, Orange, CA, USA

1 INTRODUCTION

Although initially slow to become established, magnetic resonance imaging (MRI) now plays a vital role in the diagnostic imaging evaluation of many pediatric diseases and disorders. The ability to produce multiplanar images in a noninvasive manner without the use of ionizing radiation and with only minimal patient preparation has made MRI a useful complement to other cross-sectional modalities such as ultrasound and computerized tomography (CT). The most frequent indications for an MRI study in the pediatric population include the evaluation of congenital anomalies and the characterization of tumors and other mass lesions.

2 CONGENITAL ANOMALIES

MRI plays an important role in evaluating both complex congenital anomalies, where ultrasound is inadequate, and simple congenital anomalies, where sonography is not possible, is incomplete or is suboptimal. Congenital anomalies are well visualized with MRI due to its provision of excellent anatomical detail and its multiplanar capabilities. The majority of lesions are adequately assessed using multiplanar T_1 - and T_2 -weighted spin echo imaging. Occasionally, additional sequences are required, especially if the presence of fat or flowing blood is to be determined.

The ability of MRI to differentiate vessels containing flowing blood from other mediastinal structures without the use of bolus injection of contrast material makes it an ideal choice for evaluating anomalies of the great vessels.^{1,2} Preoperative mapping may alleviate the need for angiography in selected patients. In addition, in such lesions as the double aortic arch and the right aortic arch with an aberrant left subclavian artery and a left ligamentum arteriosum, MRI can evaluate for the presence of esophageal and/or tracheal compression that may be associated with these lesions. In the entity known as the 'pulmonary sling', where the left pulmonary artery arises from the right pulmonary artery and passes between the trachea and the esophagus, the presence of tracheal compression may be similarly assessed. Other, more rare, symptomatic abnormalities, as well as the asymptomatic great vessel anomalies can also be evaluated. In patients with a right aortic arch, MRI can determine the presence or absence of mirror image branching and can demonstrate any associated cardiac anomalies. Cardiac gated T_1 -weighted images in the axial and coronal planes can often provide sufficient information for these diagnoses to be made, although sometimes images parallel to the course of the aorta are very useful.

The most common congenital pediatric abnormalities involving the lung include congenital lobar emphysema, cystic

adenomatoid malformation, and sequestration. The first two entities can be evaluated using MRI, although plain film radiography and/or CT examination are usually sufficient. MRI, however, can be very useful in cases of sequestration, as it may be able to demonstrate the anomalous feeding vessels and draining veins.³ The corresponding lung tissue may appear solid or aerated on MRI, depending on its connection, if any, with the bronchial tree.

Abnormalities of the diaphragm, such as diaphragmatic hernias and eventrations, can also be evaluated by MRI. Coronal and/or sagittal T_1 -weighted images are useful in determining the presence or absence of a portion of the diaphragm, as well as identifying which, if any, of the normal abdominal components are in the chest.⁴ In patients with anterior abdominal wall defects, such as gastroschisis and omphalocele, MRI can be used to determine which abdominal organs have protruded through the defect and define their position (Figure 1).

In the abdomen, congenital anomalies of the hepatobiliary system such as choledochal cysts, biliary atresia, and polycystic liver disease can all be evaluated using MRI, but are more commonly diagnosed using ultrasound. MRI plays a more important role in the visualization of abnormal vascular anatomy in such anomalies as the Budd–Chiari malformation and discontinuity of the inferior vena cava. In the Budd–Chiari malformation, MRI may identify obliteration of the hepatic veins and may help determine if a congenital web or a thrombus is responsible for the condition.

In the retroperitoneum, abnormalities in renal position and development are readily seen with MRI. Renal ectopia, whether high (intrathoracic) or low (pelvic) can be differentiated from renal agenesis more easily with MRI than with ultrasound, since visualization of the abdominopelvic cavity by MRI is not limited by the presence of bowel gas or bone, as it is with ultrasound. Fusion anomalies, such as crossed fused ectopia and horseshoe kidney are also well demonstrated by MRI.^{5–7} Crossed fused ectopia, like most congenital renal anomalies, is best imaged using coronal T_1 -weighted images, and is diagnosed when an abnormally positioned fused kidney is visualized on one side and there is no identifiable renal tissue on the contralateral side. Horseshoe kidneys, on the other hand, are easier to diagnose on axial T_1 -weighted images, as the fusion of the lower poles is often more apparent in this plane. In children with renal agenesis, the ipsilateral adrenal gland develops a discoid rather than a chevron-shaped appearance, and can be seen as an elongated linear structure on coronal magnetic resonance (MR) images.⁴

Although all of the renal cystic diseases can be demonstrated using MRI, ultrasound remains the primary imaging modality for this class of diseases. MRI is most useful in clarifying confusing cases and in demonstrating complications such as hemorrhage. Simple renal cysts appear as homogeneous, well-defined masses on the MR image and are of low signal intensity on T_1 -weighted sequences and of very high signal intensity on T_2 -weighted sequences. The cyst wall and the fluid in the cyst may be indistinguishable. If hemorrhage into the cyst occurs, or if the cyst has a high protein concentration for another reason, inhomogeneous high signal intensity can be demonstrated on both T_1 - and T_2 -weighted sequences. Despite these guidelines, there is a wide range of variability in the appearance of hemorrhagic cysts, and in some cases it is not

Figure 1 Omphalocele. (a) Sagittal view (SE 350/11): multiple loops of bowel and a large volume of the liver have herniated into the omphalocele sac. (b) Axial view (FSE 4000/102Ef): liver (L), gall bladder (GB), bowel (B), spleen (Sp) and stomach (St) are identified in the omphalocele sac. (c) Coronal view (SE 350/12): both kidneys are abnormally superior in position, lying just below the diaphragm

always possible to distinguish a hemorrhagic cyst from an infected cyst or even from a neoplasm.

MRI is an excellent modality for the evaluation of congenital anomalies of the genital tract. In disorders of sexual differentiation, MRI can clearly show the absence of, or abnormal location of, pelvic organs in children with ambiguous genitalia or genetic abnormalities.⁷⁻⁹ Imaging in both the axial and sagittal planes, and with both T_1 - and T_2 -weighted sequences is often necessary in these patients with Turner syndrome, testicular feminization, hermaphroditism, or one of the various forms of pseudohermaphroditism.

MRI can also evaluate the spectrum of Müllerian duct anomalies, ranging from uterus didelphys (two uteri, two cervixes, and two vaginas) through bicornuate uterus (two uteri, single vagina, and cervix) to uterus septus (single uterus, cervix, and vagina with a uterine septum).¹⁰⁻¹² The distinction between the last two entities is crucial if surgical intervention is planned. MRI can often make this distinction in postpubertal girls. On T_2 -weighted images in a plane axial to the body of the uterus, the bicornuate uterus will demonstrate a medium signal intensity strip of myometrium separating the two low signal intensity junctional zones that the septate uterus will not. MRI can also evaluate the urinary anomalies, such as renal agenesis or renal malposition, which are often associated with Müllerian duct anomalies.

Renal anomalies can also occur in patients with the Mayer-Rokitansky-Kuster-Hauser syndrome.¹³ In this syndrome, which is characterized by aplasia of both the uterus and upper vagina, the spectrum of renal anomalies includes unilateral agenesis, unilateral or bilateral ectopia, horseshoe kidney, malrotation, and collecting system abnormalities. Vertebral anomalies have also been reported. Because MRI can be used to evaluate the vagina noninvasively, it is the modality of choice for patients with this disorder, as well as for patients with isolated vaginal atresia.

In patients with hematometrocolpos, T_1 - and T_2 -weighted images can demonstrate a high signal intensity collection within a markedly dilated upper vagina and uterine cavity¹⁴⁻¹⁶ (Figure 2). These dilated structures may compress the adjacent bladder or rectum. The fluid collection may extend into the fallopian tube, leading to a dilated tortuous fallopian tube visualized extending into the abdomen.

MRI has also proved useful in identifying undescended testes in male children prior to surgery. Ultrasound is performed initially and, if it is unsuccessful, MRI is then performed.^{17,18} The undescended testis is usually in the inguinal canal, but if it is in the abdomen or pelvis, the testis can be adjacent to the lateral bladder wall, the psoas muscle, the iliac vessels or in the retroperitoneum or the superficial inguinal pouch. On T_1 -weighted images, the testis is of medium signal intensity and can frequently be identified if it is surrounded by fat, which is of high signal intensity. On T_2 -weighted images, the central portion of the testis is of high signal intensity with a surrounding rim of medium signal intensity, and therefore can be easily distinguished from muscles and lymphadenopathy.

Anorectal anomalies, such as imperforate anus and ectopic anus, are also well visualized using MRI. Both these disorders are due to failure of descent of the hindgut. In imperforate anus, the rectum terminates in a blind pouch, whereas in ectopic anus, the more common of the two entities, there is a fistulous connection between the pouch and another structure, such as the perineum, vestibule, vagina, urethra, bladder, or cloaca. Plain film radiography, contrast examination, and ultrasonography have all been helpful in the preoperative evaluation of these patients. MRI, however, can noninvasively give a multiplanar view of the hindgut, puborectalis sling and adjacent structures, defining the anatomy to better advantage.¹⁹⁻²² In this regard, axial and coronal T_1 -weighted images can demonstrate the anatomy of the puborectalis sling, determine whether

Figure 2 Hematomatros involving one side of a uterus didelphys. (a) Coronal view (SE 600/18): high signal intensity blood products are identified in a markedly distended uterine cavity; a second uterine cavity (arrows) with an endometrial stripe is identified compressed on the right. (b) Axial view (FSE 4000/102Ef): the distended left uterine cavity occupies most of the volume of the pelvis, displacing the left ovary (Ov) anteriorly

Figure 3 Mediastinal teratoma. (a) Coronal view (SE 625/11): a mediastinal mass is identified with locules of differing signal intensity; a few small foci of bright signal intensity are noted within the mass. (b) Coronal view (SE 625/11, chemical lipid presaturation): using a lipid-selective presaturation pulse, the formerly bright areas in the lesion become dark, verifying that they represent fat; the presence of fat in the lesion histologically characterizes it as a teratoma

or not it is hypoplastic, and define its relationship to the hind-gut.

3 TUMORS AND OTHER MASS LESIONS

Due to its multiplanar capability, its ability to distinguish vessels with flowing blood from other structures, without the need for bolus injection of contrast material, and its superior contrast resolution compared with that of CT, MRI is an extremely useful tool in the evaluation of mass lesions.⁴ Once a lesion has been discovered on a chest radiograph or on an ab-

dominal or pelvic ultrasound, MRI can help to characterize the lesion, identify the organ of origin, define its extent, clarify its relationship to adjacent vessels, and evaluate for distant metastasis. MRI can classify a lesion as either cystic, solid, or mixed. Although some solid lesions such as teratomas, lipomas, and hemorrhagic lesions may demonstrate characteristic MR appearances, the majority of solid lesions are impossible to differentiate using signal intensity alone. Most such solid lesions are of medium signal intensity on T_1 -weighted images and of high signal intensity on T_2 -weighted images. However, when the signal characteristics of a lesion are combined with information about its organ of origin, its relationship to adja-

cent vessels and/or its sites of metastasis, a definitive diagnosis can often be made. MRI can be used before treatment, to plan a surgical approach or a radiation port, as well as after treatment, to assess for residual or recurrent tumor after surgery, chemotherapy and/or radiation therapy.

Gadolinium chelate contrast agents may be useful in characterizing vascular masses and in evaluating renal and perirenal lesions.²³ In these instances, T_1 -weighted images obtained dynamically during, and/or immediately after, intravenous contrast administration may more clearly define the borders of the lesion, characterize its internal architecture, accentuate surrounding adenopathy, and/or uniquely define the histology of the lesion.

In the thorax, MRI is particularly useful in the evaluation of masses arising in the posterior mediastinum, as it may noninvasively demonstrate the presence or absence of intraspinal extension.^{24,25} These posterior mediastinal masses are most frequently of neurogenic origin and include such entities as neuroblastoma, ganglioneuroma, and neurofibroma. They are all of medium signal intensity on T_1 -weighted images and of high signal intensity on T_2 -weighted images. Coronal and axial images are useful in demonstrating intraspinal extension, if any, and in clarifying the relationship of the lesion to adjacent vasculature.

MRI can also demonstrate lesions in the anterior and middle compartments of the mediastinum, and may even have a slight edge over CT in selected cases.²⁶ For example, coronal and/or sagittal images may help define the extent of neck masses that secondarily involve the mediastinum or lung apices. These lesions include cystic hygroma, hemangioma, and fibromatosis. Fat selective sequences may also be helpful in distinguishing mediastinal teratomas from other mass lesions (Figure 3). Additionally, as with posterior compartment masses, MRI may help clarify the relationship of the lesion to adjacent vessels and other structures, due to its multiplanar capability, its ability to distinguish vessels with flowing blood from other structures, without the need for bolus injection of contrast material, and its superior contrast resolution.

In the abdomen and pelvis, MRI is an excellent modality with which to differentiate masses arising from the liver, kidney, adrenal gland, and paraspinal regions. Some of the more common lesions arising from these areas warrant discussion.

In children with hemangioendotheliomas, MRI can often demonstrate the mass in the liver and may be able to map the feeding and draining vessels. An abrupt caliber decrease in the abdominal aorta distal to the origin of the celiac axis may also be observed.⁴ Serial imaging after gadolinium chelate administration can often uniquely identify the hepatic lesion as a hemangioendothelioma due to its distinctive temporal pattern of peripheral to central enhancement.

The most common malignant tumors of the liver, hepatoblastomas and hepatocellular carcinomas, can also be evaluated using MRI. Both lesions demonstrate variable signal intensity on both T_1 - and T_2 -weighted images (Figure 4). Because MRI can usually identify the portal and hepatic veins, it can assess for vascular invasion by the tumor and can also define the extent of the tumor with respect to the segmental anatomy of the liver, thus aiding in determining resectability of the lesion.

Wilms' tumor is the most common solid abdominal mass and the most common primary renal neoplasm in children, with a peak incidence between the ages of 1 and 3 years. An increased incidence of Wilms' tumor is noted in children with aniridia, hemihypertrophy, neurofibromatosis, genitourinary abnormalities, and the Beckwith-Wiedemann syndrome. The tumor presents most often as a unilateral abdominal mass, although the lesion is bilateral in 5–10% of cases. The initial diagnosis is usually made by ultrasound, which demonstrates a solid renal mass. MRI, however, may be superior to both ultrasound and CT in diagnosing and defining the extent of Wilms' tumor.^{27,28} In this area of the body, coronal T_1 -weighted images can often define the organ of origin of a lesion extremely well, separating renal lesions from those arising in the adjacent liver or adrenal gland. With a combination of coronal and axial planes, and T_1 - and T_2 -weighting, a study can define the full extent of the lesion, its possible invasion of adjacent organs or vessels, as well as assess for the presence of associated lymphadenopathy. In selected cases, intravenous administration of a gadolinium chelate and/or use of MR angiographic techniques may be necessary.²³

Neuroblastoma is the most common extracranial solid malignant tumor in children. Neuroblastoma and its more differentiated forms, ganglioneuroblastoma and ganglioneuroma, arise from primitive sympathetic neuroblasts and therefore may

Figure 4 Hepatoblastoma. (a) Coronal and (b) sagittal (SE 300/20) views: a large mass, heterogeneous in signal intensity, projects inferiorly from the liver and invades the portal vein; the speckled high signal intensity areas probably represent hemorrhage. (c, d) Axial views (SE 2500/30,80): although markedly heterogeneous, the lesion is predominantly low in signal intensity

Figure 5 Neuroblastoma. (a) Coronal view (SE 300/16): an enlarged right adrenal gland (arrows) displaces the right kidney inferiorly. (b) Axial view (FSE 2500/17Ef): the liver is also enlarged and filled with metastases, leading to a salt and pepper heterogeneity to its signal intensity

Figure 6 Neuroblastoma. (a) Coronal view (SE 616/15): a large multilobulated medium signal intensity mass surrounds the aorta, displacing it and the inferior vena cava to the right and anteriorly. (b) Axial view (SE 2128/15): a portion of the mass is seen extending into the bony spinal canal (arrow); the left psoas muscle (P) is elevated and displaced to the left by this high signal intensity tumor

arise from the adrenal gland (most commonly) or from anywhere else along the sympathetic chain from the nasopharynx to the presacral region. Children with neuroblastoma may present with a palpable abdominal mass or with symptoms referable to metastases, such as bone pain. The staging of neuroblastoma is based on both local extent as well as on the presence or absence of metastases. Clinically, however, it is more important to determine resectability of the lesion, as surgery remains the treatment of choice. On MRI, neuroblastoma is usually of medium signal intensity on T_1 -weighted images and of high signal intensity on T_2 -weighted images. It is less well defined than Wilms' tumor and if it arises from the adrenal gland it can displace the kidney inferiorly and/or laterally (Figure 5). As with Wilms' tumor, MRI can play a role in defining the full extent of a lesion, identifying its organ of origin, assessing for possible invasion of adjacent organs or

vessels, and demonstrating the presence or absence of metastases.^{29–31} Evidence of tumor extending into the spinal canal or encasing the retroperitoneal vessels can classify the neuroblastoma as unresectable (Figure 6).

Neonatal adrenal hemorrhage is another entity that may present as an asymptomatic abdominal mass. Differentiation of neonatal adrenal hemorrhage from neuroblastoma is crucial, and can usually be done using ultrasound or MRI. On ultrasonography, neonatal adrenal hemorrhage is usually anechoic and avascular, in contradistinction to neuroblastoma, which is usually echogenic and vascular. In some instances, adrenal hemorrhage does not appear cystic on ultrasonography and MRI may be extremely useful in helping to make this distinction. On MR images neonatal adrenal hemorrhage behaves similarly to hematomas elsewhere in the body, with a changing MR appearance as the hematoma evolves (Figure 7). More

Figure 7 Neonatal adrenal hemorrhage. (a, b) Coronal views (SE 450/11): an enlarged right adrenal gland (arrows) is identified (a) that does not demonstrate enhancement after gadolinium administration (b). (c) Coronal view (FSE 4000/102Ef) and (d) axial view (FSE 3500/102Ef): blood products in varying stages of oxidation are identified in the enlarged right adrenal gland (arrows)

Figure 8 Presacral teratoma. (a) Sagittal view (SE 800/23): a presacral mass is identified with components that are hypointense, isointense, and hyperintense to muscle. (b) Sagittal view (SE 800/16, chemical lipid presaturation): using a lipid-selective presaturation pulse, the formerly hyperintense component is suppressed to the same degree as the adjacent subcutaneous fat; the presence of fat in the lesion histologically characterizes it as a teratoma. (c) Sagittal view (FSE 3000/102Ef): the presence of chemical shift spatial misregistration can also be used to verify the presence of fat in this lesion (arrows); when this artifact is present, lipid-selective presaturation pulses are not necessary to characterize the lesion

specifically, on T_1 -weighted images acute hematomas are isointense to muscle, whereas subacute hematomas are hyperintense to muscle. Neuroblastoma usually demonstrates homogeneous medium signal intensity on T_1 -weighted images. On T_2 -weighted images, neonatal adrenal hemorrhage may be of high signal intensity or of low signal intensity, depending on the chemical state of the blood products. In rare cases of cystic neuroblastoma with hemorrhage, however, the distinction may be difficult. In these cases, evaluation of the liver for the presence of metastasis (low signal intensity on T_1 -weighted images and high signal intensity on T_2 -weighted images) may help make the diagnosis of neuroblastoma.

Rhabdomyosarcoma is the most common pediatric soft tissue sarcoma and can occur in almost any primary site except the brain. In children, it is most frequently found in the pelvis and genitourinary tract or in the head and neck. In the genitourinary tract, the tumor most frequently arises in the bladder; other common sites are the urethra, prostate, and vagina. Bladder lesions most commonly arise from the submucosa of the trigone or the bladder base and then infiltrate the bladder wall and adjacent structures including the urethra, prostate, vagina, and uterus. Because of the propensity for local invasion, it can be difficult to determine if the primary site was the bladder or the prostate in males or the bladder or the vagina in females. The multiplanar capabilities of MRI make it well suited for demonstrating bladder wall thickening, demarcating the inferior, lateral and posterior extent of the tumor, and detecting distant metastases.^{6,24}

Sacrococcygeal teratomas are the most common tumors of the caudal region in children. These lesions are derived from all three germinal cell layers and have a characteristic MR appearance. Specifically, on T_1 - and T_2 -weighted images a large presacral mass is identified that contains rounded, well-defined areas of different signal intensity. Often one of these locules will contain fat, which can be demonstrated using a lipid-selective presaturation pulse or by simply looking for chemical shift misregistration. (Figure 8). Since these lesions displace the rectum anteriorly, as do all lesions in the presacral space, they can be distinguished from lesions arising in the pelvic cavity. The differential diagnosis for presacral masses in infants also includes anterior meningocele, rectal duplication, neuroblastoma, lymphoma, and lipoma.

4 SUMMARY

During the relatively short time that MRI has been applied to the evaluation of pediatric diseases and disorders, it has proven to be a useful tool in the diagnostic evaluation of a variety of entities, many of which we have touched upon in this article. More detailed information about some of these diseases and disorders can be found in the references given at the end of this article, and it is the authors' hope that the reader will learn from these references and, perhaps in time, add to them.

1 INTRODUCTION

Phosphorus-31 MRS provides a noninvasive method of assessment of mobile phosphorus-containing compounds. A typical in vivo ^{31}P MR spectrum contains seven resonances (Figure 1). Phospholipid cell membrane precursors, adenosine monophosphate (AMP) and glycolytic intermediates (sugar phosphates) contribute to the phosphomonoester (PME) peak. Phospholipid cell membrane degradation products and endoplasmic reticulum contribute to the phosphodiester (PDE) peak. Information on tissue bioenergetics can be obtained from inorganic phosphate (Pi), phosphocreatine (PCr) and the three nucleoside triphosphate resonances. A measurement of intracellular pH (pHi) can be calculated from the chemical shift of the Pi peak.

Figure 1 An unlocalized ^{31}P MR spectrum from the head of a healthy adult volunteer. There are seven resonances. PME, phosphomonoester; Pi, inorganic phosphate; PDE, phosphodiester; PCr, phosphocreatine; ATP, adenosine triphosphate

Pathological processes involving hypoxia and ischemia are particularly amenable to ^{31}P MRS assessment using absolute or relative quantitation of the PCr and Pi peaks. The PCr/Pi ratio has been the most commonly used marker of tissue energy reserve under these conditions. Phosphorus-31 MRS may also provide an indication of the viability of isolated donor organs prior to transplantation.

In this article, we discuss the role of in vivo ^{31}P MRS in the examination of tissue bioenergetics in human studies.

2 ^{31}P MRS AND CELLULAR ENERGY STATUS

The energy metabolism of each cell is dependent on the synthesis and utilization of compounds which contain high-energy phosphate bonds such as ATP and PCr.¹ ATP is present in all cells, but PCr is limited to those tissues containing creatine and the enzyme creatine kinase (CK), such as skeletal muscle and brain. ATP has a pivotal role in cellular bioenergetics. The demand for ATP is usually reasonably constant under normal resting conditions. The hydrolysis of ATP to ADP (adenosine 5'-diphosphate) and Pi releases potential energy from high-energy phosphate bonds for all activities involved in maintaining intracellular homeostasis and the specialized functions which may be unique to each cell type. Phosphocreatine acts as an energy reservoir in tissues such as muscle and brain. The enzyme CK splits PCr to provide an energy source for ATP resynthesis (Figure 2). Oxidative phosphorylation, which involves an electron transport chain in the mitochondrial membrane, is the process which provides most of the ATP for each cell under conditions of adequate oxygen supply. In a range of situations the requirements for ATP cannot be met by oxidative phosphorylation in the mitochondria. For example, oxidative phosphorylation is impaired in hypoxia and may be inadequate in normal exercising muscle. The shortfall in ATP production is met by glycolysis in the cytoplasm. Lactic acid may accumulate as a consequence of this process. Phosphocreatine is utilized under these conditions and as PCr falls, Pi increases, but any reduction in ATP is minimized because of the buffering effect of CK. Only when the PCr pool is completely consumed do the tissue ATP levels fall appreciably, leading to a rise in both ADP and Pi.

Figure 2 The interrelationship between ATP and PCr. Cr, creatine; CK, creatine kinase; ADP, adenosine diphosphate

Mitochondrial oxidative metabolism may also be affected by changes in pH_i ,² but the rate of ATP biosynthesis remains constant under normal conditions. The concentration of ADP is a major factor in the rate of ATP production.^{2,3} The majority of ADP is not directly detectable using NMR methods because of tissue binding. The ability of a particular tissue to synthesize ATP may be calculated from the phosphorylation potential, given by equation (1)

$$[ATP]/[ADP][P_i] \quad (1)$$

A further indication of cellular energy status is given by equation (2):

$$[PCr]/[Cr][P_i] \quad (2)$$

Absolute or relative concentrations of tissue PCr, P_i , and ATP can be obtained using ^{31}P MRS. The rate of ATP biosynthesis, the phosphorylation potential, ADP concentrations, and the kinetics of CK may be calculated from ^{31}P MRS measurements.^{2,3} The PCr/ P_i and PCr/ATP ratios are commonly used MR indices of cellular energy status or 'bioenergetic reserve', as they reflect equations (1) and (2).

The oxidative phosphorylation pathway can be assessed using the PCr/ P_i ratio. Glycolytic intermediates contribute to the PME peak and therefore an indirect assessment of glycolysis may be obtained from quantitation of this resonance. This is of particular importance in assessment of glycolytic disorders in muscle and in dynamic studies of liver metabolism.

3 ^{31}P MRS AND INTRACELLULAR pH

Phosphorus-31 MRS can be used to measure intracellular pH from the chemical shift of the P_i peak with reference to the PCr resonance in tissues such as brain and muscle where PCr is present. In tissues such as liver where PCr is absent the reference used is α ATP. The MR signal from P_i is thought not to represent the total intracellular levels of P_i . It is unclear why the remainder is not detected, but it may be bound in the mitochondria. It is not known whether there are pH differences between the cytoplasm and the mitochondria. Split P_i resonances representing intracellular compartmentation have not been observed in human ^{31}P MRS in vivo.

Different body tissues are more susceptible to ischemia and hypoxia than others. In normal exercising muscle, anaerobic glycolysis may take place with the accumulation of lactic acid as a normal sequence of events. The large PCr reservoir in muscle ensures an energy source for these anaerobic reactions. The accumulation of lactate in the brain is more likely to be of pathological consequence because cerebral function is particularly sensitive to hypoxic insults. The measurement of intracellular acidosis may be used as a marker of hypoxia-ischemia and cellular dysfunction in conditions such as stroke or birth asphyxia. Under these circumstances, the PCr/ P_i ratio is reduced. Lactate accumulation leads to a reduction in pH_i and a change in the chemical shift of P_i . Intracellular pH may change with time: for example, an intracellular alkalosis can develop in ischemic brain tissue of stroke patients over an extended time period.⁴ The underlying mechanisms behind such pH changes are not known. However, the MR measurement of pH_i may be used to discriminate between diseased and

healthy tissue in combination with indices of bioenergetic reserve such as PCr/ P_i .

4 ^{31}P MRS AND PHOSPHOLIPID METABOLISM

The PME and PDE peaks are multicomponent. Phosphoethanolamine (PE) and phosphocholine are cell membrane precursors and contribute to the PME peak with signal from glycolytic intermediates and AMP. Glycerophosphorylethanolamine (GPE) and glycerophosphorylcholine (GPC), which are cell membrane degradation products, contribute to the PDE resonance. Phosphoenolpyruvate and endoplasmic reticulum form other contributory factors. The relative contributions of these compounds to the PME and PDE peaks may change with disease. In situations where there is rapid cell turnover, the PME resonance may be elevated due to an increase in PE and phosphocholine. Similarly, under conditions of rapid cell death, after tumor embolization or chemotherapy, for example, an increased contribution of GPE and GPC to the PDE peak may be expected. Phosphorus-proton decoupling can be used to resolve further these resonances in vivo.

5 ^{31}P MRS AND TRANSPLANT ORGAN VIABILITY

Organ transplantation is a steadily expanding surgical field. Increased patient survival rates have been achieved because of improved operative techniques, anti-rejection chemotherapy, and methods for harvesting and preserving donor organs.

The success of any transplant procedure is dependent on the quality of the donor graft and this is a reflection of organ storage methods. The use of more physiological preservation fluids has led to increased storage times, allowing donor organs to be transported between transplant centers. Despite these advances, tissue damage, caused by cold preservation, is an important factor in patient morbidity and mortality. Phosphorus MRS provides a noninvasive assessment of the viability of the isolated donor organ prior to transplantation. The standard indices of bioenergy reserve such as PCr/ATP and PCr/ P_i ratios may be appropriate markers in heart transplantation, but the ^{31}P MR spectra from healthy liver and kidney contain no appreciable PCr. Therefore, other indices such as the PME/ P_i ratio have to be employed. Adenosine 5'-triphosphate begins to degenerate to ADP and P_i immediately each organ has been harvested. With time, ADP further degenerates to AMP which contributes to the PME peak. The PME/ P_i ratio may reflect the ability of the isolated organ to rephosphorylate AMP to ATP on transplantation. Specific transplant studies are considered later in this chapter.

6 CLINICAL APPLICATIONS

The development of whole body magnets has allowed clinical ^{31}P MRS studies to be undertaken in patients with a variety of pathological processes, facilitating comparisons with healthy volunteers and offering the possibility of disease monitoring in response to treatment. MR measurements of bioenergetic reserve such as the PCr/ P_i ratio have been proposed as predictors of outcome in hypoxic and/or

ischemic conditions such as birth asphyxia. A review of the role of ^{31}P MRS in some of the major disease processes follows.

6.1 ^{31}P MRS and the Adult Brain

6.1.1 Stroke

Stroke is the most common adult neurological condition and is a prominent cause of mortality in developed countries. Early diagnosis of ischemia facilitates more appropriate treatment, and delay may result in an irreversible loss of neuronal function. Ischemia and the consequent tissue hypoxia result in a depletion in PCr, ATP levels being maintained initially. The acute stages of stroke are characterized by a decreased PCr/Pi ratio in the ^{31}P MR spectrum and an intracellular acidosis.⁵ These changes may be detectable before MRI changes become evident.⁵ A combination of ^{31}P MRS and MRI may aid early diagnosis, and help to monitor the brain's response to treatment.

Persistent cerebral ischemia results in irreversible cell damage and neuronal death. A reduction in phosphorus signal has been seen in patients with chronic stroke, consistent with a reduction in viable cells in the area of infarction.⁴ The pH_i has been noted to change with time, resulting in a rebound intracellular alkalosis which may persist.⁴ The reasons underlying this change remain unclear.

6.1.2 Transient Ischemia

A transient ischemic attack is defined as a reversible neurological deficit that lasts for 24 h or less. The diagnosis is therefore retrospective and treatment is aimed at preventing recurrence. One study of two patients suggested that the total phosphorus signal was reduced in the absence of MRI changes.⁴ This may be due to ischemia, but remains difficult to explain.

6.1.3 Epilepsy

Temporal lobe epilepsy may be unresponsive to standard antiepileptic therapy and a small number of patients require surgical resection of the epileptogenic focus. The definition of the pathological area needs careful preoperative planning. MRI studies have been used to obtain hippocampal volumes⁶ but the role of ^{31}P MRS has been limited. A reduced PME, probably as a result of underlying hippocampal sclerosis, has been noted in some studies. An increased Pi and an unexplained intracellular alkalosis have been noted in most studies,^{4,7} all of which have involved relatively small numbers of patients.

6.1.4 Alzheimer's Disease

The results of ^{31}P MRS studies have been disappointing. Bottomley and colleagues⁸ found no changes in either metabolite ratios or absolute concentrations of metabolites.

6.1.5 Multiple Sclerosis

This condition is common in temperate climates and is characterized by episodes of focal neurological deficit which relapse and remit over a period of many years. The classic histological lesions are plaques of demyelination. MRI has

revolutionized the diagnosis of this condition, but the results of ^{31}P MRS studies are less clear-cut. In one study⁹ there was a decrease in the PCr/ATP ratio in some patients with active disease, whereas in another study¹⁰ there was an increase in the PCr/ATP ratio with disease activity.

6.1.6 Other Cerebral Conditions

Decreased PCr/Pi has been observed in the cerebral ^{31}P MR spectra from patients with migraine and mitochondrial cytopathies. This suggests an alteration in bioenergetic reserve.

Chronic hepatic encephalopathy is defined as the neuropsychiatric impairment observed in patients with cirrhosis of the liver. The results of some ^{31}P MRS studies have suggested altered brain energy metabolism in these patients (see also *Systemically Induced Encephalopathies: Newer Clinical Applications of MRS*).

6.2 ^{31}P MRS and Pediatric Brain Studies

The normal ^{31}P MR spectrum from a healthy neonatal brain is significantly different from adult spectra. The PME signal is much larger in the neonate and this varies with gestational age. Azzopardi and colleagues¹¹ found that the PME is smaller and the PDE larger in the healthy full-term infant than the healthy preterm infant, related most probably to the changes in membrane lipids with myelin formation. The PCr/Pi ratio increases with gestational age, indicating an increased phosphorylation potential with brain development. The measured intracellular pH appears not to vary with the gestational age of healthy newborn infants.

6.2.1 Hypoxic-Ischemic Encephalopathy

Birth asphyxia of the newborn infant has been extensively investigated using ^{31}P MRS. This condition is almost unique because there are well-defined MR indices of prognosis. Reduced PCr/Pi ratio has been correlated with outcome.¹² Spectra obtained in the initial 24 h after birth may be normal, but a fall in PCr and a rise in Pi (reduced PCr/Pi ratio) may develop over the ensuing hours and days (Figure 3). This reflects defective oxidative phosphorylation as a result of birth trauma. Intracellular pH tends to rise in a delayed response to the hypoxic-ischemic insult and there may also be a reduction in ATP levels. The metabolite ratios tend to return to normal within 2 weeks in neonates who recover. The reduction in PCr/Pi ratio is proportional to the degree of subsequent neurodevelopmental impairment and to reduced cranial growth in the first year of life.¹² In the severest cases, where the neonates subsequently die, the PCr and ATP may be almost undetectable. The Pi often rises out of proportion to the reduction in PCr. This delayed or secondary response to ischemic injury is poorly understood, but may be partly due to the toxic effects of neurotransmitters such as glutamate, which may induce mitochondrial membrane disruption through the generation of free radicals.¹³ Phosphorus-31 MR spectroscopy may be utilized to monitor the effectiveness of treatment designed to prevent this secondary energy failure. The development of suitable therapeutic regimens is an area of current and future research. However, the PCr/Pi ratio is already being used as a predictor of patient outcome and may give the pediatrician insight into planning future management decisions.

Figure 3 An unlocalized ^{31}P MR spectrum from the head of a birth asphyxiated neonate. The PCr peak is reduced and the Pi peak is elevated

6.3 Myocardial Metabolism

Heart muscle is well supplied with oxygen and mitochondria. It relies on glycolysis to a much smaller extent than skeletal muscle, which has a higher concentration of glycolytic enzyme and fewer mitochondria. The regulation of cardiac metabolism and its relation to mechanical function has been widely studied in animals and humans^{14,15} (see also *Cardiovascular NMR to Study Function* and *NMR Spectroscopy of the Human Heart*).

6.3.1 Measurements in Normal Myocardium

Some of the major problems encountered in cardiac studies are related to signal contamination of the myocardium from the chest wall and from blood circulating through the cardiac chambers. The chest wall contains about four times more PCr than the normal myocardium. Signal from blood usually includes appreciable amounts of ATP and PDE, and an intense 2,3-diphosphoglycerate (2,3-DPG) resonance, which may obscure the Pi and PME resonances. Under such circumstances the pH_i and the PCr/Pi ratio cannot be measured.¹⁶

Inorganic phosphate and pH_i measurements still remain difficult in humans. Localization techniques may be used to minimize signal contamination from chest wall or blood. Correction for residual blood contamination and saturation effects may also be made.

The PCr/ATP ratio is the most frequently used index of bioenergy reserve in cardiac studies. Results from human and animal studies are comparable.¹⁷ This ratio remains relatively constant during the cardiac cycle and in exercise. It is also highly reproducible. The PDE/ATP ratio is difficult to measure accurately because of interference from the 2,3-DPG signal. The available data show considerable biological variation in human studies. Different examination techniques may compli-

cate this matter. The pH_i of normal human myocardium is pH 7.15 ± 0.03 .¹⁸

6.3.2 Measurements in Myocardial Diseases

Spectral abnormalities in human myocardium mainly reflect ischemic conditions.¹⁹ The PCr/ATP ratio decreases significantly during hand grip exercise²⁰ in patients with a high degree of coronary artery stenosis. This ratio is also reduced in advanced stages of heart failure, in left ventricular hypertrophy, or dilated cardiomyopathy.²¹ An increase in normal PCr/ATP ratio has been shown during treatment for heart failure.¹⁷ Apart from blood contamination, an increased PDE/ATP ratio might reflect an accumulation of cell membrane degradation products in patients with a decreased left ventricular ejection fraction.²²

6.3.3 Cardiac Transplantation

Advances in operative technique and in antirejection therapy have led to cardiac transplantation being used as a viable treatment for patients with end-stage heart disease. Endomyocardial biopsies with histological grading are the gold standard for detection of rejection. No reliable noninvasive alternative is available at present. Phosphorus-31 MRS has been studied in this context.

Animal models of cardiac transplantation have demonstrated an early decrease in PCr/ATP and PCr/Pi ratios.²³ A parallel rise in PDE/ATP was found in two studies which preceded the onset of histologically detectable rejection by 1 or 2 days.^{23,24} The increase in the PDE peak measurements may be due to immunological or reperfusion injury. The abnormalities of high-energy phosphate during acute, severe rejection are reversible with antirejection therapy.²⁵

In human studies no correlation was found between the decrease in the PCr/ATP ratio measurements and the biopsy grading. Severe rejection may therefore not be distinguishable from mild or moderate rejection by ^{31}P MRS alone.²⁶ The discrepancy between animal and human studies may be explained by the different time courses for MRS examinations and the rather more heterogeneous human population and study conditions.

6.4 ^{31}P MRS and the Kidney

Spectral localization is required because there are considerable regional differences in renal function and metabolism. The cortex is dependent on oxidative phosphorylation and the inner medulla is more reliant on glycolysis for energy requirements. Localization has proved difficult owing to the anatomical position and the displacement on respiratory excursion. No large-scale studies have been undertaken in the renal failure patients, but transplanted kidneys are positioned in a relatively superficial, static position in the anterior pelvis and are therefore much more amenable to MRS examination.

The normal ^{31}P MR spectrum does not contain a large PCr signal arising from the kidney. There is a relatively large PME peak compared with liver and muscle. Urinary Pi may contribute to the PDE resonance, but this only becomes significant when the collecting ducts are distended through obstructive disease.²⁷

6.4.1 The Isolated Donor Kidney

Phosphorus-31 MRS can be used to assess the viability of isolated donor organs, kept in physiological preservation fluid, prior to transplantation. An alternative index of tissue energy reserve has to be used because the renal PCr pool is small. Adenosine 5'-triphosphate degrades to ADP and Pi fairly rapidly, but provided there is sufficient cellular AMP, rephosphorylation to ATP should be possible. Adenosine monophosphate resonates in the PME region of the spectrum and therefore the PME/Pi ratio has been used as an indicator of viability. Human studies have positively correlated the PME/Pi ratio with subsequent postoperative renal function.²⁸ The best renal function was observed in kidneys where ATP was seen in the donor organ spectra.

6.4.2 The Transplanted Kidney

Phosphorus-31 MRS may be used to investigate renal failure, graft rejection, or organ viability postoperatively. The PME/ATP ratio may be slightly higher in the transplanted kidney than in healthy volunteers. Animal studies have shown an elevated Pi/ATP ratio with renal failure or ischemia due to poor graft viability. Organ rejection or renal dysfunction due to cyclosporin toxicity may produce a similar picture.²⁷ Such changes are nonspecific, but perhaps may be used to monitor the effectiveness of antirejection chemotherapy.

6.5 ³¹P MRS and Liver

The position of the liver renders it much more amenable to MRS investigation. The MR spectrum contains no PCr signal arising from the liver itself. Most studies have concentrated on changes in PME/ATP and PDE/ATP ratios with disease, reflecting changes in hepatic phospholipid and carbohydrate metabolism. The Pi/ATP ratio remains relatively constant. Clinical interest has focused on spectral changes under conditions such as alcoholic liver disease, cirrhosis, primary and secondary liver tumors, and the dynamic changes in metabolites following infusions of fructose, alanine, and alcohol. This subject is discussed in detail in another article (see *In Vivo Hepatic MRS of Humans*). Tissue behavior measurements have been used to measure the effectiveness of chemoembolization therapy for hepatic cancers. The resulting ischemia can be assessed using PME/Pi or PME/ATP ratios, both of which fall after successful treatment.²⁹

The PME/Pi ratio has been used to assess the viability of isolated donor organs prior to transplantation in a similar fashion to the renal studies already mentioned.³⁰

6.6 ³¹P MRS in Tumors

The difficulty with reporting metabolic changes in tumors, as reflected by ³¹P MRS, is that the results are variable, depending on the size, location, and precise histology. In human tumors, the typical metabolite characteristics include lower PCr and higher PME and PDE levels.³¹ Variations in the PME and PDE levels may reflect different rates of membrane synthesis, catabolism, or metabolic turnover. (See also *Spectroscopic Studies of Animal Tumor Models; In Vivo Hepatic MRS of Humans*; and *Brain Neoplasms in Humans Studied by Phosphorus-31 NMR Spectroscopy*).

The PCr/Pi ratio is reduced in most high-grade tumors of the brain, reflecting an increased demand for ATP in rapid growth. The measured pHi is often found to be alkaline under these circumstances.³² The reasons for this intracellular alkalinization remain unclear.

Treatment such as radiotherapy or chemotherapy may induce hypoxia, ischemia, or necrosis in tumors. These changes may lead to an increase in Pi³³ and acidosis.³⁴ The early decrease in PME seems to be a sensitive indicator of changes in the phospholipid metabolism of the cell membrane.³¹ However, because of the wide interindividual variability, changes should be related to initial measurements performed in patients before the start of therapy.

6.7 ³¹P MRS and Muscle

Phosphorus-31 MRS allows investigation of muscle bioenergetics at rest, during exercise, and during the recovery period. Normal muscle has a low metabolic rate and a high energy capacity at rest, reflected in a high PCr/Pi ratio. During exercise the ATP levels are maintained at the expense of the PCr pool. Anaerobic glycolysis results in lactate accumulation and a reduced pHi. In the recovery phase PCr regenerates and the PCr/Pi ratio rises to preexercise levels. The observed pHi also returns to normal, because oxidative phosphorylation then provides the bulk of the energy requirements. Phosphorus-31 MRS may be utilized as a screening test in patients with exercise intolerance. The various muscle pathologies are discussed in a separate article (see *Peripheral Muscle Metabolism Studied by MRS*). We briefly consider some of the major conditions where tissue behavior measurements are important.

6.7.1 Mitochondrial Myopathies

Mitochondrial myopathies, where there is defective oxidative phosphorylation, are characterized by a reduced resting energy state and a decreased PCr/Pi ratio, which falls rapidly to very low levels on exercise.³⁵ The capacity for exercise is reduced and the resynthesis of PCr after exercise is impaired, because this is dependent on mitochondrial function. Therefore there is a prolonged recovery phase before the PCr/Pi ratio reaches resting levels. Intracellular acidosis is often observed, which may become marked on exercise.

6.7.2 Glycolytic Disorders

Specific enzyme deficiencies in the glycolytic pathway block the production of lactic acid and therefore the pHi does not fall in anaerobic exercise as it does in normal muscle. This failure of intracellular acidification is characteristic.³⁵ During exercise an accumulation of glycolytic intermediates can be measured indirectly from the ³¹P MR spectrum, because sugar phosphates contribute to the PME resonance.

7 CONCLUSIONS

In vivo ³¹P MRS provides a noninvasive assessment of tissue bioenergetics and phospholipid metabolism. Comparisons may be made between healthy and diseased tissue. Measurements of the PCr/Pi ratio and pHi may provide insights into

pathogenic mechanisms and in the future, the efficacy of therapeutic intervention in cardiac and cerebral hypoxic-ischemic states. Energy reserves at rest and during exercise may be monitored in muscle disease, and the PME/Pi ratio is a noninvasive indicator of viability in isolated donor organs prior to transplantation. In vivo ^{31}P MRS remains predominantly a research tool, but it has proved to be clinically useful in birth-asphyxiated babies and in studies of muscle disease.

Imaging and Spectroscopy of Muscle

Chris Boesch and Roland Kreis

University of Bern, Switzerland

1 INTRODUCTION

Examinations of extremities and skeletal muscle have been among the first applications of NMR in the human body. At the advent of in vivo NMR, magnets were available with sufficiently high field strength for magnetic resonance spectroscopy (MRS) but their limited bore size allowed only small animals or human extremities to be examined. The development of surface coils (see *Spatial Localization Techniques for Human MRS*) allowed localized acquisition of NMR signals—a technique that was mainly used for ^{31}P MRS and to a lesser extent for ^{13}C MRS. For a while, classical ^{31}P MRS experiments (see *Peripheral Muscle Metabolism Studied by MRS, Tissue Behavior Measurements Using Phosphorus-31 NMR*) were the major application of MRS and led to a substantial contribution to knowledge in muscle physiology. In the following years, the development of whole-body magnets introduced NMR applications to clinical medicine (see *Whole Body Studies: Impact of MRS*). MRI of extremities, muscle tissue, and joints became a routine diagnostic tool (see *ESR Probes as Field Detectors in MRI, MRI of Musculoskeletal Neoplasms, Skeletal Muscle Evaluated by MRI*). The combination of MRI and MRS in whole-body magnets led not only to improved anatomical localization defined by gradients but also to better description of the sensitive volume by MRI in the same magnet. The wider bore of these systems allowed for examinations of larger muscle groups, for example those of the thigh. Gradient-based volume selection and improved localization sequences particularly promoted the development of ^1H MRS methods.

The number of NMR applications in perfused muscles and animals is huge but will not be covered in this chapter, which focuses on human skeletal muscle. At present, publications on ^{31}P MRS in small-bore and whole-body systems still represent a considerable portion of the physiological applications of MR (see also *Peripheral Muscle Metabolism Studied by MRS*). An increasing number of new applications, however, combine and use other MR techniques and other nuclei. Some of these applications will be described in this chapter.

2 STRUCTURAL ORDER AND COMPARTMENTATION IN MUSCLE TISSUE

Skeletal muscle is a biological structure that is highly organized at different spatial levels. (a) Skeletal muscles are composed of various types of muscle fiber with inherently different composition and metabolism. (b) Bulk fat along fasciae around muscles forms macroscopic plates that run almost parallel with the axes of extremities. (c) Muscle fibers may

extend parallel to the muscle ('fusiform' arrangement) or with a certain 'pennation' angle between muscle and fibers ('unipennate' with one major direction or 'bipennate' if two different types of fiber orientation exist that are attached to one tendon). (d) Myofibrils form the well-known striated structures (sarcomeres) including actin and myosin molecules, which are spatially organized on the microscopic level. (e) Membranes and cell organelles such as mitochondria separate a specific metabolite from the same metabolite in the cytoplasm, leading to different pools and transport processes.

Structural order and compartmentation in biological tissue can influence MR signals such that measurable parameters or artifacts are generated, depending on the way the experiment and observer are using or neglecting that information. Several effects, which will be discussed below, can be attributed to structure or compartmentation.

1. the relaxation times of muscle, tendons, and cartilage, depend on fiber orientation and type;¹⁻³
2. the muscle- or subject-specific metabolite content, energy kinetics, and recruitment pattern based on distributions of fiber types;³⁻⁷
3. the isotropic and ordered compartments, as distinguished by ^{23}Na double quantum filtered (DQF) MR spectra;^{8,9}
4. susceptibility effects, which are different for extramyocellular (bulk) (EMCL) fat and for intramyocellular lipids (spherical droplets) (IMCL);^{10,11}
5. magnetization transfer (MT) of the invisible fixed pool of molecules to the moving and visible pool;¹
6. restricted diffusion measurable by specialized MRI and MRS sequences;¹²⁻¹⁶
7. the dipolar coupling effects of creatine (Cr) and/or phosphocreatine (PCr) resonances owing to anisotropic motional averaging;^{17,18}
8. differences in the NMR visibility of Cr/PCr and other metabolites as a result of compartmentation and/or limited motional freedom.¹⁹⁻²¹

MR is a unique tool with which to investigate order and compartmentation in biological tissues. Even if these are not the major target of a specific examination, their effects should always be kept in mind when interpreting images and spectra.

3 USE OF MRI FOR HUMAN MUSCLE PHYSIOLOGY

3.1 MRI for Volume Localization

The combination of MRI and MRS improves the anatomical localization of spectra considerably. MRS examinations in small-bore systems often have to rely on palpation and approximate positioning of the surface coil. With appropriate imaging sequences, it was possible to show that palpation incorrectly identified flexor muscle margins by more than 15 mm in 50% of attempts.²² In principle, MRI makes it possible to place the region of interest with an accuracy of about 1 mm. Even if images are acquired prior to MRS, it may not be feasible to place the sensitive volume of a surface coil with the same precision. However, the subsequent use of gradient-based localization schemes and a proper fixation of the examined extremity allow for a volume selection within adequate

accuracy. Since the fiber orientation, composition, and activation are muscle specific and can vary even within one muscle,²³ combined MRI/MRS systems are, therefore, necessary to obtain MR parameters from one specific muscle type, as shown in several examples below.

3.2 Activity-dependent MRI

The amount and distribution of water in skeletal muscle is changed by muscular activity.^{2,23–27} Subsequent variations in relaxation times make MR signal intensity highly sensitive to changes in the water distribution, oxygenation, pH, and other factors. Fleckenstein et al.²⁸ suggested imaging parameters with which it was possible to detect and document muscular activity (see also *Skeletal Muscle Evaluated by MRI*). This technique can be used to study intersubject variations of normal anatomy and muscular activation. Ergometers to be used in an MR system have to be redesigned to fit into the restricted space of the patient bore. The technique described can help to document the activity imposed by such an ergometer. While it is clear that activity-dependent MRI is a valuable and practical tool to investigate muscular activity, it is not so clear which changes in MR parameters lead to this effect. It seems that water inflow and pH changes contribute only partially to the observed increase in T_2 relaxation.^{25,27}

3.3 Muscle Volume Determination using MRI

Muscle mass is a variable parameter and is dependent on training, ageing, temporary immobilization, disease, and other factors. Knowing muscle mass is, therefore, crucial for an estimation of training effects and also for calculations of total body content of metabolites and components of the muscular cell. Many localized observations of physiological parameters, such as biopsies, need additional data on the absolute volume of the muscle, since changes in concentration could be a result of increased muscle mass (i.e. simple dilution with unchanged total content) or an effective increase in total content.

It is obvious that MRI with its excellent soft tissue contrast is predestined to be used for in vivo morphometric measurements.^{4,29–33} However, all approaches have specific advantages and disadvantages, for example three-dimensional versus multislice techniques, nonlinearity of the spatial representation, different ways of image analysis, and partial volume effects.

The image acquisition can be done either by three-dimensional sequences or using sequential two-dimensional data (i.e. multislice techniques) (Figure 1). As long as discrete slices are evaluated, the so-called Cavalieri principle needs to be respected.³¹ It states that the starting point of a series of slices should be arbitrarily set such that every position has equal probability. This avoids systematic over- or underestimation of a volume through specific sampling of the structure.

In principle, images can be measured in one acquisition as long as the muscle does not exceed the homogeneous volume of the magnet, which is typically about 50 cm in diameter. However, the linearity of the gradients within the homogeneous volume and subsequently the accuracy of the mapping is significantly reduced in the outer portions of the volume because of the nonlinearity of the gradients. Therefore, imaging of

larger muscles may be more appropriate in multiple steps. The imperfect spatial accuracy of MR systems is usually improved by retrospective image-correction algorithms, which use the known spatial characteristics of the gradients. This procedure is acceptable for diagnostic images where the relative positions are much more important than the absolute dimensions. For quantitative measurements, however, a continuous monitoring of these effects is necessary, especially if variations over longer time periods are investigated, such as training effects on muscular volume.

The cross-sectional area and actual volume can be determined by several methods:^{29,31–33} simple threshold, voxel counting within operator-defined borders, elaborated tissue segmentation algorithms, or point counting. Simple threshold methods need a homogeneous rf sensitivity of the coil since substantial inhomogeneities in signal intensity will lead to wrong assignment of voxels. Computed tissue segmentation, often based on different MRI scans, uses several steps to distinguish between tissues, in many cases with human interaction. Image intensity threshold can be followed by boundary tracing, edge detection filters, morphological erosion, seed-growing algorithms,^{29,30} etc. Point counting³¹ is an interactive method very popular in morphometry, for example to analyze electron micrographs. Grids are placed over the region of interest (Figure 1) and crosses that hit the structure of interest are counted. The probability for a hit is proportional to the area covered by the structure. If large enough numbers are counted (typically over 100 hits per structure), variations resulting from the counting procedure are negligible and the number of hits represents the desired area almost perfectly. Point counting is a very robust method but is very time consuming and, to a certain extent, operator dependent.

All digitization methods are somewhat susceptible to partial volume effects: the misinterpretation of voxels that contain more than one type of tissue. If a T_1 -weighted MR sequence is used that leads to a strong signal of fat, voxels that are only half filled with adipose tissue will produce sufficient signal to be counted as fat. Since this happens in all voxels at the border of fat and muscle tissue, fat content will be systematically overestimated. Optimized imaging sequences and appropriate windowing of the signal intensity may help to reduce this problem.

3.4 Use of MRI for Determination of Muscle Fiber Orientation and Composition

In addition to assessment of gross morphology, histological characterization of muscle tissue by means of MR is desirable. So far, fiber orientations in muscle and the 'pennation angle' between muscle fibers and axis of the muscle have been measured by ultrasound. It has been proposed that MR images would show sufficient morphological detail to see striations generated by fat, which runs parallel and between the muscle fascicles, and that this would allow for an assessment of the fascicle pennation.^{4,33} One interesting finding of such a three-dimensional analysis was a considerable variation of pennation angles within one muscle;⁴ for example a range of 5 to 50° was observed in the vastus medialis. This noninvasively obtained information helps to evaluate muscle mechanics. Further suggestions have been made to use the effect of

Figure 1 Selected axial slices of the lower leg with an illustration of morphometry based on the point counting method. A grid is placed arbitrarily over the anatomical structure to be measured—here the tibialis anterior muscle—and points lying within the structure of interest are counted. The number of counted points is proportional to the volume of the structure when a series of slices is evaluated. The error introduced by the placement of the grid and the counting becomes negligible if more than 100 points are counted overall

anisotropic diffusion^{1,14,16} within heart or skeletal muscle tissue to visualize fiber orientation in MR images.^{13,15}

So far, fiber composition has mainly been assessed by ^{31}P MRS using differences in PCr content and pH (see *Peripheral Muscle Metabolism Studied by MRS*). The method requires relatively large sensitive volumes and, therefore, it is inherently susceptible to partial volume effects: a mixture of signals from different muscles that are partially activated and resting. Activity-dependent MR images and gradient-based volume selection may improve these observations in future.

The determination of fiber composition by MRI is based on differences in relaxation times of water.³ Using the effect of gadolinium diethylenetriamine pentaacetic acid (DTPA) on MR

images of rabbit muscle, larger extracellular space has been observed in slow-twitch (red) muscle (see *Skeletal Muscle Evaluated by MRI*).⁷

4 USE OF MRS FOR HUMAN MUSCLE PHYSIOLOGY

4.1 The Use of Different Nuclei to Observe Muscular Metabolism

The high-energy phosphates visible in the ^{31}P MR spectrum and the pH titration of the inorganic phosphate (Pi) relative to

PCr made ^{31}P MRS the favorite tool for biochemists and physiologists interested in muscular metabolism (see *Peripheral Muscle Metabolism Studied by MRS*).

The application of ^{13}C MRS for examinations of muscular metabolism attracted the attention of physiologists because glycogen is 100% visible in the ^{13}C MR spectrum despite the very large molecular weight of this molecule. However, the technical requirements for ^1H -decoupled ^{13}C MRS are considerably higher than those usually provided in a standard clinical scanner.

Until recently, there had only been some exploratory studies using ^1H MRS. This is particularly remarkable since ^1H is the most frequently used nucleus in brain examinations. Originally, the reasons for this obvious disinterest were of a technical nature (water suppression, eddy currents for short echo times), but later the sparse attention to ^1H MRS of muscle may have resulted from a general feeling that its information content would be rather low. It will be shown below that this impression was wrong.

Other nuclei such as ^{23}Na have only rarely been used to study muscle metabolism.^{8,9} However, we expect that studies of order on the molecular level will benefit from the potential of less popular nuclei in the future.

Some very elegant examinations of muscular metabolism use combinations of different nuclei, for example ^{13}C with ^{31}P MRS:^{34–37} the ^{13}C studies follow the depletion and recovery of glycogen while ^{31}P is used to monitor phosphorylation. Combinations of different nuclei and the fusion of MRS and MRI in the same session will be vital approaches in the future development of MR of human muscle metabolism and will prove the enormous versatility of MR.

4.2 Classical ^{31}P MRS of Human Muscle

Many of the classical studies of human muscle using ^{31}P MRS are covered in other monographs in these volumes and these provide a wide range of references to work in this area (see *Peripheral Muscle Metabolism Studied by MRS, Phosphorus-31 Magnetization Transfer Studies In Vivo, Proton Decoupling During In Vivo Whole Body Phosphorus MRS, Single Voxel Whole Body Phosphorus MRS, Tissue Behavior Measurements Using Phosphorus-31 NMR, Whole Body Studies: Impact of MRS, pH Measurement In Vivo in Whole Body Systems*). The first report on a muscular disease documented by ^{31}P MRS—McArdle disease—promoted the application of MRS in vivo. However, widespread distribution of ^{31}P MRS in clinical routine and the use of this modality in all-day diagnostics did not occur as expected and it remained an excellent, but somewhat specialized, tool for research in physiology and pathology.

Beside the well-known observation of high-energy phosphates by ^{31}P MRS and the determination of intracellular pH, MT experiments have also examined the creatine kinase reaction (see also *Phosphorus-31 Magnetization Transfer Studies In Vivo*). The very recent development of genetically manipulated mice (e.g. creatine kinase knock-out mice) may help in the understanding of many aspects of ^{31}P MRS.

Proton decoupling during acquisition of phosphorus spectra (see *Proton Decoupling During In Vivo Whole Body Phosphorus MRS*) allows signals such as those from glycerophosphorylcholine and glycerophosphorylethanolamine

to be distinguished, which may help to improve understanding of membrane metabolism.

Diffusion-weighted ^{31}P MRS of PCr and Pi—together with MT techniques—may provide more information on the creatine kinase reaction and the role and nature of Cr/PCr as energy shuttle, reservoir, or buffer in the myocyte.

4.3 Application of ^{13}C MRS in Human Muscle

The main application of ^{13}C MRS in human muscle has been the observation of glycogen depletion and repletion, with and without labeling of blood glucose at the C1 position by ^{13}C , and in some experiments controlled by clamp techniques.^{38–40} Specific labeling of other compounds and subsequent isotopomer analysis has been very successful in whole animals and isolated organs but has hardly been used in humans. Despite the fact that ^{13}C MRS is extremely useful and elegant, only a few groups worldwide are using this method in studies of human metabolism. This can be explained by the technical requirements (broadband acquisition, ^1H decoupling) and by the low signal-to-noise ratio (SNR), which would benefit from field strengths higher than those available in routine scanners. Studies with substrates labeled with ^{13}C are expensive and clamp studies require additional experience. The increasing number of MR systems at field strengths of 3–4.7 T will hopefully overcome the technical limitations and prove the value of ^{13}C MRS studies.

Four main factors characterize ^{13}C MRS: (a) the low gyromagnetic ratio, which is about 25% of that of ^1H ; (b) the low natural abundance of ^{13}C (most carbons are NMR invisible in the form of ^{12}C); (c) the large chemical shift dispersion of about 250 ppm compared with about 10 ppm for ^1H ; and (d) the direct chemical bonds to ^1H of most ^{13}C atoms. All these factors have methodological consequences. The low gyromagnetic ratio leads not only to a lower resonance frequency but also to an inherently low sensitivity of ^{13}C , which is about 0.016 compared with ^1H . The natural abundance of 1.1% for ^{13}C further reduces signal intensity. However, the low natural abundance does not only have negative consequences; it also allows for the use of ^{13}C -labeled substrates as tracers, which is obviously not feasible for ^1H or ^{31}P . The large chemical shift dispersion per se is advantageous since the separation of different resonances increases. This makes an unspoiled observation of a specific metabolite much easier than in the much more crowded ^1H MR spectrum. However, the large chemical shift dispersion leads to a spatial misregistration that may be intolerable when popular gradient-based volume localization methods are used directly. The fact that gradients have not been widely used for localization of ^{13}C MR spectra is also a consequence of the very short T_2 of glycogen; the signals would have decayed at echo times that are typically used in point-resolved spectroscopy (PRESS) or stimulated echo acquisition (STEAM) sequences. (For additional information on localization sequences see *Spatial Localization Techniques for Human MRS*). The use of image-selected in vivo spectroscopy (ISIS) overcame the problem of fast transverse relaxation since the magnetization is kept in the longitudinal direction during the localization procedure.⁴¹ Localization of ^{13}C nuclei can also be accomplished indirectly via the coupled ^1H nuclei and subsequent polarization transfer.^{42–46} Because of very short ^1H T_2 , these methods are not useful for localization of glycogen. Most

Figure 2 Carbon-13 MR spectrum of the thigh at 1.5 T (GE SIGNA, Milwaukee, WI), without (lower trace) and with (upper trace) continuous wave decoupling of the protons (decoupler S.M.I.S., UK). The decoupling and NOE build up of the doublet of glycogen C1 leads to an improved signal-to-noise ratio that allows a reduction of measurement time (lower trace 10 000 scans, upper trace 4000 scans)

applications, therefore, apply surface coils for localized transmission and reception of the signals, using pulse-and-acquire sequences. Nevertheless, volume localization of ^{13}C MR spectra is often a critical issue for several reasons: (a) adjacent muscle groups may have differences in metabolite levels but usually contribute to an overall signal; (b) huge signals from subcutaneous fat may mask the tiny resonances from metabolites (e.g., signal contributions from muscular glycogen in the abdominal wall may not be separable from liver glycogen); (c) sensitivity profiles of surface coils are complicated and make absolute quantification much more difficult than methods with a rectangular shape of the selected region. Some methods use bottles filled with known solutions that replace the human body to calibrate the metabolite levels;⁴⁷ others use Cr as an internal standard.⁴⁸ The chemical bonds between carbon atoms and adjacent ^1H lead to substantial heteronuclear spin-spin coupling and to splitting of the resonance lines, which further reduce the amplitudes. With ^1H decoupling by irradiation on a second rf channel, it is possible to cancel the coupling effect, restoring the full resonance amplitude (Figure 2). In addition, irradiation on the ^1H frequency prior to acquisition leads to the so-called nuclear Overhauser enhancement (NOE), which results in an additional 50–90% in signal intensity⁴⁹ under in vivo conditions (Figure 2).

Glycogen is a large molecule with a molecular weight of 10^7 to 10^9 . Since macromolecules are usually not visible by MRS because of their very short T_2 relaxation, it was surprising that glycogen turned out to be 100% visible.^{50,51} It seems that the internal molecular mobility leads to effective decoupling from fast relaxation processes. The observation of glycogen in human muscle (and liver) is meanwhile one of the 'workhorse' applications of in vivo MRS. NOE effect and short repetition times guarantee a reasonable SNR within approximately 10 min even at 1.5 T. Higher field strengths, however, are desirable to increase SNR and/or temporal resolution.

Studies of noninsulin-dependent diabetes mellitus (NIDDM) patients³⁶ showed a slower glycogen repletion compared with healthy volunteers. Combination with ^{31}P MRS was then used to identify the limiting step in glycogen synthesis more closely (see below). Patients suffering from glycogen storage diseases^{48,52} were found to have higher levels of glycogen in muscle and liver. Studies on normal subjects^{37,43,47,53,54} revealed important physiological information on glycogen as an energy reserve for the human muscle, for example changing with different diets, with different exercise intensity, and as a function of the insulin-dependent and independent control mechanisms.

Studies of lipid metabolism using ^{13}C MRS would be very attractive since the degree of saturation and chain length could be evaluated.^{55–57} However, the difficulties in separating signals from subcutaneous adipose tissue and muscular lipids (IMCL, see below) restrict this method to studies of bulk fat so far.

Since ^{13}C has a very low natural abundance, substrates can be enriched at specific positions in the molecule. This can either be used to distinguish between 'old' and 'new' fractions of a metabolite pool, e.g., to identify glycogen that is newly built in the muscle, or it can be used to distinguish between several potential biochemical pathways. One of the most popular applications is labeling of glucose at the C1 position and the follow-up by ^{13}C MRS during its incorporation into muscular glycogen in clamp studies.^{36,50}

Most ^{13}C labeling experiments with subsequent isotopomer analysis (i.e., analysis of the coupling patterns of mixtures of the same compound with different degrees of labeling), have been done in animals, perfused organs, or plasma samples.^{58–63} An example in skeletal muscle is the observation of $[1-^{13}\text{C}]$ -glucose incorporation into intramuscular $[1-^{13}\text{C}]$ -glycogen, $[3-^{13}\text{C}]$ -lactate, and $[3-^{13}\text{C}]$ -alanine.⁵⁹ Carbon-13 MRS requires much higher enrichment of the ^{13}C isotope than does mass spectrometry; it does, however, have the advantage of organ selectivity (e.g., compared with analysis of breathing air) and chemical specificity.

4.4 Application of ^1H MRS in Human Muscle

4.4.1 General Features

Proton MR spectra of skeletal muscle were believed to be swamped by the large signal from fat, which would render all other metabolites invisible. Recent work has shown that the spectrum is indeed very complex, but it is rich in information and reflects several aspects of the physiology of exercise.

A typical ^1H MR spectrum of human muscle tissue acquired by a PRESS sequence (see *Spatial Localization Techniques for Human MRS*) is shown in Figure 3. Based on high-resolution spectra of muscle extracts and in vivo rat and frog muscle, the peaks visible in spectra of human muscle in vivo have been assigned early on^{5,64–68} to the following compounds: lipids (methyl protons 0.9 ppm, aliphatic chain methylene protons 1.3 ppm, aliphatic protons near double bonds and carboxyl group at 1.7–2.5 ppm and protons of unsaturated carbons at 5.4 ppm); Cr/PCr (methyl at 3.03 ppm (Cr3), methylene at 3.93 ppm (Cr2)); trimethylammonium group-containing metabolites (TMA), such as choline, phosphocholine, glycerophosphocholine, and carnitine at 3.2 ppm; a line that has been tentatively assigned to taurine at approximately 3.4 ppm, depending on the orientation of the muscle; and two his-

Figure 3 PRESS-localized ^1H MR spectrum of the human tibialis anterior muscle. The orientation of the fibers in this muscle parallel to the magnetic field leads to the separation of the signals from intra- (IMCL) and extramyocellular lipids (EMCL), and the splitting of the creatine (methylene Cr2, methyl Cr3) resonances. Trimethylammonium (TMA) covers one part of the Cr3 triplet and the coupling partner of resonance X3, which can be tentatively assigned to taurine. Acetylcarnitine at 2.13 ppm is not visible at rest; while lactate at 1.3 ppm is only visible with editing techniques and during workload/ischemia

tidine protons of the dipeptide carnosine at 7.0 and 8.0 ppm (anserine in some species). A peak at the unusual position of 78 ppm (Figure 4), which is invisible under the experimental conditions used for Figure 3, could be detected and assigned to deoxymyoglobin.^{69,70} Lactate at 1.3 ppm can also be observed only under specific experimental conditions.^{6,21,68,71–73}

As seen above, skeletal muscle is highly organized at different spatial levels and many aspects of order influence ^1H MR spectra. These aspects are summarized in a previous paragraph and for the different metabolites separately below.

4.4.2 Lactate

The signal of the methyl group of lactate is overlaid by the much larger signals from lipids in human muscle. However, using the hetero- or homonuclear spin–spin interaction and editing techniques by inversion and decoupling,⁶⁸ zero- or double-quantum filters^{6,21,71–73} are able to observe the lactate signal without the huge overlapping resonances. Promoted by the physiological importance of this metabolite, observations of lactate have been among the first applications of ^1H MRS in human muscle.

4.4.3 pH

A second important parameter for the description of muscular metabolism is the intracellular pH, usually determined by

Figure 4 (a) Spectra showing the resonance of deoxymyoglobin from the lower leg in a patient with peripheral arterial disease. (b) Signal development during ischemia and recovery proximal and distal to the lesion (au, arbitrary units). Arrows indicate time points when the spectra shown on the left were acquired. The time resolution in the graphs is 3.5 s, one spectrum represents a 16 s acquisition (30 Hz apodization). The time constant for recovery is 10 s proximal and 36 s distal from the lesion (unpublished data; clinical support by Dr I. Baumgartner is greatly appreciated)

the frequency difference between Pi and PCr in the ^{31}P MR spectrum. Proton MRS provides the same information, since the aromatic signals of histidine in the carnosine molecule are titrating and can, therefore, be used to determine intracellular pH. A comparison between titration observed in ^{31}P and ^1H MR spectra⁶⁸ showed the accuracy of ^1H MRS. Because of the fairly low concentrations of carnosine, the ^1H MRS measurement may be less sensitive than ^{31}P MRS during exercise. However, ^1H MRS has the advantage of identical sensitivity independent of exercise scheme, while the undershoot of Pi after exercise and the low Pi content in resting muscle can make pH measurements with ^{31}P MRS impossible in some instances.

4.4.4 Myoglobin

Proton ^1H MRS can also be used during exercise or ischemia to estimate the degree of intracellular oxygenation by measuring deoxymyoglobin resonances. The signals from oxy-myoglobin are in the normal frequency range of an ^1H MR spectrum and, therefore, are overlapped by many other resonances at 1.5 T. Only at 7 T, the resonance of the γ -methyl group of Val-E11 at -2.8 ppm can be observed separately under oxygenated conditions.⁷⁴ However, while this resonance disappears with deoxygenation, the F8 proximal histidyl N- δ proton shifts to 78 ppm,^{69,70,75} and becomes visible also at moderate field strength. This histidine resonance has dramatically shortened T_2 relaxation times and is, therefore, very broad, but the chemical shift separation from the large resonances between 0 and 10 ppm is sufficient to detect it reliably. Figure 4 shows the increase of deoxymyoglobin during ischemia in human skeletal muscle, observed at 1.5 T.

4.4.5 Acetylcarnitine

After heavy workload, a peak at 2.13 ppm can be detected in localized spectra of human muscle,⁷⁶ while spectra from resting muscle do not feature a sharp singlet at this position in general. Based on its chemical shift, its singlet nature, its approximate concentration, and physiological behavior, the peak was tentatively assigned to the acetyl group of acetylcarnitine.⁷⁶ Carnitine has long been known for its vital role in the transportation of fatty acids into mitochondria for β -oxidation. More recently, it was recognized that carnitine is equally important as a buffering system for a potential surplus of acetyl groups.⁷⁷ The export of acetyl groups in the form of acetylcarnitine out of the mitochondria helps to keep the acetyl CoA/coenzyme A ratio balanced such that the nonacetylated form of the co-factor can play its roles in the TCA cycle and in pyruvate dehydrogenation.

4.4.6 Creatine

Considering the concentration and chemical shift differences of Cr and PCr in muscle tissue, one could expect that the resulting signals would be well above the noise level and would represent the sum of both, i.e., total Cr, since these species would not be separable at 1.5 T. A detailed analysis of Cr in ^1H MR spectra, however, showed several unexpected features^{17–20,78} such as an orientation-dependent dipolar splitting for several compounds that were not assigned at the very beginning.¹⁷ In a subsequent Cr-loading study,⁷⁸ one of these metabolites has been identified as Cr and/or PCr. The methyl-

ene group of Cr/PCr appears as a prominent dipolar doublet and the methyl group as a less well-defined triplet (see Figure 5). This finding was unexpected since *in vivo* MRS had been seen as spectroscopy of metabolite solutions where dipolar coupling is averaged out and dipolar effects are restricted to relaxation processes. Using more elaborate methods such as one-dimensional zero- and double-quantum filtering, two-dimensional J -resolved spectroscopy, two-dimensional constant time COSY, and longitudinal order separation spectroscopy,¹⁸ it was possible to prove unequivocally that peaks of Cr methylene result from a pair of dipolar coupled protons.⁷⁸ Most other resonance peaks, including the methyl group of Cr, were also found to be—at least partially—dependent on the angle between muscle fibers and magnetic field. The form of the orientation dependence and the approximate size of the coupling have been confirmed at a higher field in rat muscle.¹⁹ One can now speculate about the mechanisms behind the observed effects. Irrespective of the chemical nature of the metabolites involved, there are three main explanations to account for incomplete temporal averaging of dipolar couplings. First of all, the observed molecules may be hindered from isotropic tumbling by being constrained into small elongated spaces between the actin/myosin chains. Second, they might be temporarily bound to macromolecules that themselves are strictly ordered within the muscle cells. Finally, dipolar-coupled peaks might originate from large molecules that are permanently bound to ordered structures in muscle but have enough side-chain mobility to be observable and partially average dipolar couplings. The most likely explanation of the three is that PCr and/or free Cr together with their hydration spheres are large enough to be hindered from isotropic tumbling in the elongated

Figure 5 Spectra from the same voxel in the tibialis anterior muscle show the effect of orientation upon creatine Cr2 (methylene) and Cr3 (methyl). The lower spectrum has been acquired with the leg parallel to the magnetic field, the upper spectrum at the magic angle (54° between muscle and field). At the magic angle, splitting owing to dipolar coupling vanishes. TMA, trimethylammonium; X3 tentatively assigned to taurine

spaces between actin/myosin chains. Because of charge distributions on these molecules, specific or unspecific coupling to the actin/myosin complexes may exacerbate the ordering. It has been postulated previously that some of this space is inaccessible to PCr. Since Cr and PCr are involved in the creatine kinase equilibrium and may serve not only as a short-term energy storage but also for some forms of energy transportation, a motional restriction as observed in these experiments would be of crucial importance since the overall reaction could be limited *in vivo* by transport processes.

Additional experiments lead to further questions about the exact nature of the Cr resonances: (a) in a postmortem study of rat muscle, the doublet of Cr methylene was shown to disappear from the MR spectrum on a time scale similar to the disappearance of PCr;¹⁹ and (b) in human skeletal muscle, Cr/PCr during and after heavy exercise showed decrease and recovery similar to PCr in the ³¹P MR spectrum.²⁰ It is surprising that depletion and recovery appear to be related to the PCr content of human muscle, since the Cr signals in ¹H MRS have hitherto always been associated with total Cr, not PCr. This finding is, however, in agreement with the signal behavior observed in rat muscle postmortem.¹⁹ A straightforward but still questionable explanation for that observation would be that only the protons from PCr are detected by ¹H MRS while free Cr is invisible. The reduced visibility of Cr may or may not have similar roots to the incomplete dipolar averaging, MT effects, restricted diffusion, anisotropy of relaxation times, and the questioned visibility of lactate. The calculation of ADP concentrations based on ATP, free Cr, pH, and the creatine kinase reaction constant would be questionable if reduced visibility of Cr was an indication for reduced availability of this substrate. Therefore, findings on reduced visibility of creatine would have a serious effect on the modeled phosphorylation kinetics derived from ³¹P MRS.

Diffusion-weighted spectroscopy may be another tool to identify restricted motion of specific metabolites. An excellent overview of diffusion effects in human muscle can be found in Nicolay et al.¹² This study shows restricted motion of PCr compared with water in rat hindleg muscle.

4.4.7 Intramyocellular Lipids

IMCL are stored in droplets in the cytoplasm of muscle cells and are a form of stored energy readily accessed during long-term exercise. When Schick et al.¹¹ compared the lipid resonances in calf muscle and fat tissue, they observed two compartments of triglycerides with a resonance frequency shift of 0.2 ppm. They assigned the resonance at 1.5 ppm to lipids in fat cells and hypothesized that the resonance at 1.3 ppm could be attributed to lipids located inside muscle cells (i.e., in their cytoplasm) experiencing different bulk susceptibility (see Figure 3). This assignment was verified by Boesch et al.¹⁰ who demonstrated that IMCL signals scale linearly with voxel size, water and Cr signals, while EMCL signals do not. Furthermore the resonance frequency shift of EMCL and the orientation dependence of their spectral pattern could be attributed to the spatial arrangement of these lipids (plate-like structures for EMCL versus spheroid droplets for IMCL). Experimental data agree very well with theoretical estimations of susceptibility effects. Inter- and intraindividual reproducibility studies indicate that the error of the method is about 6% and that IMCL levels differ significantly between identical muscles in different

Figure 6 Depletion and repletion of intramyocellular lipids (IMCL) in tibialis anterior muscle after strenuous exercise (3 h bicycle training). In this example, the recovery phase of IMCL can be characterized by an exponential fit with a time constant of about 40 h. Further experiments have shown that recovery is strongly dependent on the diet. Creatine levels stay constant within the experimental accuracy (au, arbitrary units; graph adapted from Boesch et al.¹⁰)

subjects, different muscles in the same subject, as well as intraindividually in the same muscle when measured at 1 week intervals. The accuracy of IMCL determination by ¹H MRS is sufficient to follow IMCL depletion and recovery after exercise in single individuals (Figure 6). Dietary modulation of IMCL levels has been investigated by biopsy studies, with the well-known advantages and disadvantages of this invasive method. A consequence of the invasiveness is the scarcity of results and follow-up measurements. With ¹H MRS it is now feasible to follow IMCL depletion and repletion more or less continuously and in different muscle groups.

A correlation of increased IMCL levels and insulin sensitivity has been shown by ¹H MRS in diabetic patients.^{79,80} Since it is not trivial to separate EMCL and IMCL, the comparison of measurements in obese patients with normal weight volunteers could be prone to systematic errors. Comparing cohorts of patients with volunteers, weight and muscular fat infiltration should be matched between the groups to avoid systematic differences between the resulting EMCL contaminations of the spectra.

5 CONCLUSIONS

MRI and MRS of muscular physiology has occurred in distinct separate centers with different equipment for a considerable time. A combination of the two complementary modalities is now developing while classical pulse and acquire ³¹P MRS has become less prominent. Multinuclear MRS in whole-body systems using combinations of MRI and MRS with elaborate MR techniques such as diffusion weighting, editing, and MT seem to lead the way to future MR studies of muscle physiology. Less popular nuclei such as ²³Na have the potential to elucidate order in biological tissues further. Decoupling of ³¹P and ¹³C spectra, and the use of whole-body magnets at higher field, have already promoted the application

of MRS in humans. This use will increase as soon as a larger number of versatile, high-field MR systems is installed.

Recent results obtained with localized ^1H MRS in skeletal muscle have shown that it is a very attractive tool to study muscle physiology both at rest and during exercise. It now appears that with ^1H MRS alone one can, in principle, determine pH, oxygenation, lactate levels, substrate use (IMCL, potentially also glycogen in addition to ^{13}C MRS), acetyl group buffering, and possibly PCr levels. It has also become thoroughly evident that the molecular basics of muscle tissue leads to most interesting NMR findings that can by no means be modeled by a single isotropic compartment consisting of an aqueous solution. Incompletely averaged dipolar couplings, reduced visibility of Cr, MT effects on Cr, the postulated compartmentation of lactate, and the susceptibility induced separation between IMCL and EMCL are all reflections of the complex and partly oriented architecture of muscle tissues, where (partial) compartmentation, chemical exchange, varying susceptibility, structural anisotropy, and protein interactions are essential ingredients.

Wüthrich); Studies in Medicine, 1977–86; M.D. University Zurich 1986. Research assistant at the University Children's Hospital in Zurich, Switzerland: Installation of a 2.35T/40 cm MR system in a clinical setting, patient-monitoring systems for pediatric and intensive care patients, MRI and MRS studies of brain development, 1985–90; Professor and Director of MR Spectroscopy and Methodology at the University of Bern, Switzerland, 1991–present. Current research specialties: in vivo spectroscopy (^1H , ^{31}P , and ^{13}C) of brain, muscle, and liver; methodology of in vivo NMR: patient monitoring.

Roland Kreis. b 1958. M.S. (diploma in chemistry) ETH (Federal Institute of Technology) Zurich, Switzerland, 1983; Ph.D. ETH Zurich, 1989 (Zero-field NMR, supervisor R. R. Ernst). Boswell Fellow at Caltech and Huntington Medical Research Institutes, Pasadena, CA, USA, 1989–91; Assistant Professor at Department for Clinical Research (MR Spectroscopy and Methodology) University of Bern, Switzerland, 1991–present. Research interests: quantitative clinical spectroscopy using methods for optimized data acquisition and probe-accessing while studying cerebral, musculoskeletal and cardiac (patho) physiology.

Imaging of Trabecular Bone

Felix W. Wehrli

University of Pennsylvania Medical School, Philadelphia, PA, USA

1 INTRODUCTION

Bone is a composite material consisting of an inorganic phase—calcium apatite, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, corresponding to about 65% of total volume—and an organic phase—essentially collagen—accounting for most of the remaining 35%. From an architectural point of view, bone can be subdivided into cortical and trabecular, the latter providing most of the strength of the axial skeleton (e.g., the vertebral column) and the portions of the appendicular skeleton near the joints. Trabecular bone is made up of a three-dimensional network of struts and plates, the trabeculae, which are on the order of 100–150 μm in width and spaced 300–1000 μm apart.

Like engineering materials, trabecular bone derives its mechanical strength from its inherent elastic properties, its volume density, and its structural arrangement. Bone is constantly renewed through a process called ‘bone remodeling’, a term referring to a dynamic equilibrium between bone formation and bone resorption, controlled by two essential types of cells: the osteoblasts—bone-forming cells—and the osteoclasts—bone-resorbing cells. During bone formation, osteoblasts eventually become imbedded in bone, turning into osteocytes, which presumably act as piezoelectric sensors transmitting signals to the osteoblasts to induce bone formation. Since the seminal work of Wolff,¹ it has been known that bone grows in response to the forces to which it is subjected (see, for example, Roesler²). Therefore, weightlessness and physical inactivity are well-known factors inducing bone loss.

The most common pathologic process leading to bone loss is osteoporosis.³ Among the various etiologies, postmenopausal osteoporosis, which results from increased osteoclast activity, is the most frequent form of the disease, afflicting a substantial fraction of the elderly female population and, increasingly, the male population. The most common clinical manifestations are fractures of the hip and vertebrae. If detected early, calcium supplements and estrogen replacement are effective forms of therapeutic intervention. Further, the development of drugs inhibiting osteoclastic activity is in progress.

Bone mineral density is the most widely invoked criterion for fracture risk assessment, typically measured by dual energy X-ray absorptiometry (DEXA), which is based on the measurement of the attenuation coefficient in a quantitative radiographic procedure, or by quantitative computed tomography (QCT). Whereas both methods measure bone mineral density with sufficient precision, neither provides information on the properties or structural arrangement of the bone. NMR, however, has the potential to probe structure as well as chemical composition of bone, both relevant to biomechanical competence.

2 DIRECT DETECTION OF BONE MINERAL BY ^{31}P NMR

The difficulties of detecting phosphorus in the solid state in vivo are considerable but do not seem insurmountable. The problems are symptomatic of high-resolution NMR in the solid state in general: a combination of long T_1 (on the order of minutes) and short T_2 (on the order of 100 μs), as well as additional line broadening by anisotropic chemical shift and dipolar coupling.

Brown et al. first demonstrated the feasibility of quantitative analysis by solid state ^{31}P spectroscopy in human limbs as a means of measuring bone mineral density noninvasively.⁴ Imaging adds an additional level of complexity, since the short lifetime of the signal demands short gradient duration, a requirement that can only be reconciled with gradients of high amplitude and large slew rates, which are both difficult to achieve in large sample volumes. Ackerman et al. produced one-dimensional spin echo images at 7.4 T with echo times on the order of 1 ms and flip-back 180° rf pulses as a means to restore the longitudinal magnetization, inverted by the phase reversal pulse.⁵ The same group of workers reported two-dimensional images of chicken bone at 6 T by means of a combination of back-projection and ^1H – ^{31}P cross polarization for sensitivity enhancement, with echo times as short as 200 μs .⁵ In the cross-polarization technique, the ^{31}P magnetization is derived from that of dipolar-coupled protons, which have shorter T_1 and thus permit shorter pulse sequence recycling times. Making use of the dependence of the cross-polarization rate on the proton–phosphorus dipolar coupling, the same workers showed that different phosphate species can be distinguished, demonstrating the presence of a minor HPO_4^{2-} species in immature chicken bone.⁷ Very recently, Wu et al. have measured three-dimensional mineral density of hydroxyapatite phantoms and specimens of bone ex vivo.⁸ While this work is at an early stage, it clearly has unique potential for nondestructive assaying of the chemical composition and its age-related changes of bone parameters that might in part explain the increased fragility of bone in older individuals.

3 IMPLICATIONS OF BONE DIAMAGNETISM ON NMR LINE BROADENING

Another approach toward assessing the properties of trabecular bone—specifically, as its architectural arrangement is concerned—exploits the diamagnetic properties of bone mineral. By virtue of the higher atomic number of its elemental composition (i.e., calcium and phosphorus), mineralized bone is more diamagnetic than marrow constituents in the trabecular marrow cavities, which consist mainly of water and lipids (i.e., oxygen, carbon, and hydrogen).

Note that in this article, the following definitions and notation will be used for the contribution from magnetic field inhomogeneity to the total dephasing rate $R_2^* \equiv 1/T_2^*$, irrespective of the notation in the original literature: $1/T_2' \equiv R_2' \approx \frac{1}{2}\gamma \Delta H_z = 1/T_2^* - 1/T_2$, with ΔH_z representing the full width at half maximum of the magnetic field histogram in the sampling volume such as the imaging voxel and R_2' the effective transverse relaxation rate.

It is well known that near the interface of two materials of different magnetic susceptibility, and depending on the geometry of the interface, the magnetic field is inhomogeneous. Among the first to investigate these effects systematically were Glasel and Lee, who studied deuteron relaxation of beads of different size and susceptibility, suspended in $^2\text{H}_2\text{O}$.⁹ Specifically, they showed that the linewidth $1/\pi T_2^*$ scaled with $\Delta\chi$, the difference in volume susceptibility between the beads and deuterium oxide. The transverse relaxation rate $1/T_2$ was found to increase linearly with reciprocal bead size, an observation that could be reconciled with diffusion in the induced magnetic field gradients. Similar phenomena were reported by Davis et al., who measured proton NMR linewidths at 5.9 T in powdered bone suspended in various solvents and found T_2^* to decrease with decreasing grain size and thus increased surface-to-volume ratio.¹⁰ Rosenthal et al. measured R_2' in specimens from human vertebrae following marrow removal and immersion in water at 0.6 T, reporting a value of 6.1 s^{-1} , more than an order of magnitude smaller than that found for powdered bone at 5.9 T.¹¹ Wehrli et al. first reported a gradient-echo-based method for measuring the line width in vivo in humans in vertebral trabecular bone marrow and found R_2^* in the vertebrae to be increased by a factor of two to three relative to those in the intervertebral discs.¹²

One of the earliest studied magnetically heterogeneous systems in biology is lung tissue, where the local magnetic field distortions are caused by air in the alveoli, and some of the concepts described here have parallels in imaging pulmonary parenchyma.¹³ Transverse relaxation enhancement from diffusion in intrinsic microscopic gradients has received increased attention in conjunction with the blood oxygenation level-dependent (BOLD) contrast phenomenon, resulting from physiologic variations of deoxyhemoglobin in capillary vessels during functional activation.^{14,15} However, since trabeculae are considerably larger than the venules of the capillary bed (100–200 μm versus 10–20 μm), and diffusion of the protons in the marrow spaces is small (on the order of $10^{-5} \text{ cm}^2 \text{ s}^{-1}$), diffusion-induced shortening of T_2 is expected to be negligible. Consequently, the effect of the susceptibility-induced inhomogeneous field is essentially line broadening.

Suppose there is a distribution $\Delta B(x,y,z)$ across the sample volume, such as an imaging voxel of dimension $\Delta x \Delta y \Delta z$; then the transverse magnetization $M_{xy}(t)$ can be written as

$$M_{xy}(t) = \frac{M_0}{\Delta x \Delta y \Delta z} e^{-t/T_2} \times \int_{\Delta x} \int_{\Delta y} \int_{\Delta z} e^{i\gamma \Delta B(x,y,z)t} dx dy dz \quad (1)$$

For a Lorentzian field distribution, the integral in Equation (1) can be described as an additional damping term, yielding

$$M_{xy}(t) = M_0 e^{-t/T_2} e^{-t/T_2'} \quad (2)$$

T_2' is, therefore, the time constant for inhomogeneity-induced spin dephasing. While the line broadening, in general, of course, is not Lorentzian, it will be seen subsequently that the assumption of a single exponential time constant is often a valid approximation.

3.1 Susceptibility of Bone

Although there is plenty of evidence for the susceptibility hypothesis, a quantitative determination of the volume magnetic susceptibility of bone has not been reported until recently. In preliminary experiments the author determined the susceptibility of bone using a susceptibility matching technique.¹⁶ For this purpose, powdered bone from bovine femoral head was suspended in a cylindrical sample tube with a coaxial capillary containing water and serving as a reference, both aligned along the axis of a superconducting magnet. Potassium ferricyanide, $\text{K}_4\text{Fe}(\text{CN})_6$, which is highly diamagnetic, was then added incrementally to the suspension. This operation resulted in a decrease in linewidth and an increase in the bulk magnetic susceptibility (BMS) shift. For concentric cylinders, the BMS shift is given as¹⁷

$$\Delta\nu = \frac{\gamma B_0}{2\pi} \frac{|\chi_d - \chi_w|}{3} \quad (3)$$

with χ_w and χ_d being the volume susceptibilities of water and ferricyanide solution, respectively. Whereas the critical concentration at which the solution matched the susceptibility of bone could not be attained owing to limited solubility of $\text{K}_4\text{Fe}(\text{CN})_6$, the matching concentration was determined by extrapolation of the line broadening–concentration curve, from which a BMS shift of $-0.95 \pm 0.13 \text{ ppm}$ was obtained (corresponding to $\chi_d - \chi_w = -2.85 \text{ ppm}$). Hence, bone is considerably less diamagnetic than calcium hydroxyapatite.

Based on these earlier experimental approaches, Hopkins and Wehrli conducted a more rigorous study to determine the absolute susceptibility of bone, with potassium chloride as the diamagnetic additive.¹⁸ Specifically, they showed that the susceptibility of the suspension, χ_{susp} , is related to the line broadening $\Gamma - \Gamma_0$ [difference between the line width in the presence (subscript p) and absence (subscript 0) of bone powder], as follows:

$$\chi_{\text{susp}} = \chi_p - \frac{1 - f_p}{f_p k H_0} (\Gamma - \Gamma_0) \quad (4)$$

where f_p represents the volume fraction of the bone powder and k is an empirical proportionality constant, which is a function of particle size, shape, orientation, diffusion, and so forth. Therefore, extrapolation of the straight line defined by equation (4) to $\Gamma - \Gamma_0 = 0$ directly provides the susceptibility of the powder. The concentration-dependent decrease in line width and increase in BMS shift is shown in Figure 1. The susceptibility of bovine rib bone was found to be $-11.3 (\pm 0.25) \times 10^{-6}$ (S.I.), indicating bone to be about 2.3 ppm more diamagnetic than water, which is somewhat less than the earlier experiments suggested.

3.2 Theoretical Considerations and Computer Modeling

Consider two adjoining materials of susceptibilities χ_m and χ_b . The induced magnetic surface charge density σ at some location on the interface between the two materials is then given as

$$\sigma = \Delta\chi H_0 \cdot n \quad (5)$$

Figure 1 Spectra of ^1H at 400 MHz from suspensions of bovine rib bone in CaCl_2 solutions of increasing volume fraction of salt, ranging from 5 to 25% (bottom to top). The dotted line spectrum offset from the top spectrum is the best fit Lorentzian line used to estimate the spectral parameters. Small symmetric resonances about the DOH reference line are spinning sidebands. (With permission from Hopkins and Wehrli¹⁸)

where $\mathbf{n}$ is the unit vector normal to the interface and $\Delta\chi = \chi_m - \chi_b$. The additional field $\mathbf{H}_i(\mathbf{r})$ resulting from the magnetic charges at the phase boundary can be estimated from the Coulomb integral¹⁹

$$\mathbf{H}_i(\mathbf{r}) = \int_S \sigma(\mathbf{r}') \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3} dS' \quad (6)$$

where the integration is over the surface S of the interface, with $\mathbf{r}'$ and $\mathbf{r}$ representing the locations of the source and field points, respectively.

The induced field is thus proportional to the difference in susceptibility of the two adjoining materials, the strength of the applied field, and the inverse square of the distance between source and field location. For an array of trabeculae, the field should be highly inhomogeneous, and a relationship is expected to exist between the magnetic field distribution within the volume of interest and the number density, thickness, and orientation of trabeculae.

Ford et al.²⁰ developed a three-dimensional model that resembles strut-like trabecular bone as found in the vertebrae²¹ to predict the line broadening behavior of protons in the marrow spaces, as a means to investigate the structural dependence of R_2' . The model consists of a tetragonal lattice of interconnected parallelepipeds ('struts') of square cross-section, differing in susceptibility from the medium by $\Delta\chi$. When oriented so that the two parallel faces of each transverse strut are normal to the direction of the applied field $\mathbf{H}_0$ then, according to Equation (5), these two faces will have uniform charge density $\sigma = \pm\Delta\chi\mathbf{H}_0$. The other faces of the transverse (and longitudinal) struts will have $\sigma = 0$, and so do not contribute to $\mathbf{H}_i(\mathbf{r})$. If the field is oriented arbitrarily relative to the lattice, all faces will be uniformly polarized, with a charge density $\sigma = \Delta\chi\mathbf{H}_0\cos\alpha$ where α is the angle between $\mathbf{H}_0$ and the unit vector normal to any given polarized surface. An analytical expression exists for the induced field given by the integral of Equation (6) for a

rectangular lamina; consequently, the total field at any one point in space can be calculated as a sum of contributions from all charge-bearing faces. In this manner, a histogram of the field for the unit cell of this lattice was obtained by randomly placing field points within the unit cell, and R_2' was calculated by fitting the Fourier transform of the field histogram to a decaying exponential. The model predicts nearly exponential decay within the experimentally practical range of echo times (about 10–50 ms). Further, R_2' is predicted to increase with both the number density of transverse struts and their thickness. Since the latter two quantities scale with material density, this finding appears unremarkable, since it would imply that R_2' merely measures bone mineral density. However, if both strut thickness and number density are varied in an opposite manner (so as to keep the material density constant), the model indicates that R_2' will increase as strut thickness decreases and number density increases. These predictions, which have been confirmed in analogous physical models,²² underscore the importance of the distribution of the material, and suggest that different etiologies of bone loss (e.g., trabecular thinning as opposed to loss of trabecular elements) might be distinguishable.

Extending the numerical approaches described above, Hwang and Wehrli computed the magnetic field distribution in trabecular bone of human and bovine origin on the basis of a surface model derived from isotropic high-resolution three-dimensional NMR images.²³ Surfaces were modeled with triangular elements of constant magnetic surface charge density, which allows the induced field to be computed from the charged surfaces. The method was applied to computing histograms of the induced fields in specimens of trabecular bone. The width of the induced field distributions was found to be narrowest when the polarizing field was parallel to the preferred orientation of the trabeculae, confirming previous experimental findings,²⁴ which provides further support for the

Figure 2 Induced magnetic field in trabecular bone from bovine tibia. (a) Shaded three-dimensional surface display derived from three-dimensional NMR micrograms. (b) Histogram of the induced magnetic field resulting from the bone's diamagnetism with respect to the marrow constituents

anisotropic nature of the effect. Figure 2 shows a histogram of the induced magnetic field, derived from three-dimensional MR micrograms of bovine tibia with the magnetic field oriented along two orthogonal directions, together with a projection image of the specimen.

The dependence of the induced field, expressed in terms of the reversible contribution to R_2' , was also investigated by Yablonskiy and Haacke, who derived an analytical expression for R_2' in a model of trabecular bone consisting of a distri-

bution of mutually orthogonal cylindrical columns and struts.²⁵ They showed that beyond a critical time within which signal decay is Gaussian, signal evolution can be described by a single exponential time constant:

$$R_2' \propto \Delta\chi H_0 \left[\varsigma_h + \left(\varsigma_v - \frac{1}{2} \varsigma_h \right) \sin^2 \vartheta \right] \quad (7)$$

where $\Delta\chi$ is the susceptibility difference between bone and marrow, ς_h and ς_v are the densities of the struts and columns, and ϑ is the angle between the magnetic field $\mathbf{B}_0$ and the columns. Yablonskiy et al. demonstrated the angular dependence of R_2' in a simple trabecular bone phantom composed of parallel polyethylene filaments and found their experimental findings to agree well with their theory.²⁶ Similar findings were reported by Selby et al. in microphantoms consisting of cylindrical Pyrex rods.²⁷ Previously, Chung et al. had demonstrated the anisotropic behavior of R_2' , in vivo in the distal radius where trabeculae are highly ordered, following the anatomic axis.²⁴ This observation was confirmed by Yablonskiy et al., who found R_2' in the radius to be twice as large with the axis of the wrist perpendicular compared with parallel to the direction of the field.²⁶

4 RELATIONSHIP BETWEEN TRABECULAR ARCHITECTURE, LINE BROADENING, AND MECHANICAL COMPETENCE

Trabecular bone is well known to be anisotropic, with the orientation of the trabeculae following the major stress lines. In the vertebrae, for example, the preferred orientation of the trabeculae is along the body axis, in response to the compressive forces acting in this direction. The role of the horizontal trabeculae is to act as cross ties preventing failure by buckling. It has also been shown that, during aging, horizontal trabeculae are lost preferentially.²⁸

If the static magnetic field is applied parallel to the inferior-superior axis of the vertebrae, the horizontal trabeculae (i.e., those orthogonal to the field) are polarized and, therefore, are expected to be the principal cause of the susceptibility-induced line broadening. Chung et al. measured the mean spacing of horizontal trabeculae (i.e., the reciprocal of horizontal trabecular number density) in cadaver specimens of human lumbar trabecular bone after bone marrow removal and suspension of the bone in water, using NMR microscopy and digital image processing.²⁹ They found a positive correlation between water proton R_2' , measured at 1.5 T, and mean number density of the horizontal trabeculae ($r = 0.74$, $p < 0.0001$).

The critical role of the horizontal trabeculae in the vertebrae in conferring compressive strength is illustrated with the correlation between R_2' measured with the polarizing field parallel to the body axis and Young's modulus of elasticity (stiffness) for compressive loading. Figure 3(a) shows the relationship between anatomic axis, trabecular orientation, the orientation of the applied magnetic field, and the direction of compressive loading. A strong association between stiffness and R_2' exists over a wide range of values ($r = 0.90$), corresponding to trabecular bone of very different morphologic composition

Figure 3 (a) Cross-section through a cylindrical trabecular bone specimen (schematic) used for R_2' , structural, and stress analysis. The cylinder axis is parallel to the anatomic inferior–superior axis, aligned with the external field polarizing predominantly horizontal trabeculae, which cause line broadening of the proton resonances in the marrow spaces. Compressive loading is applied along the cylinder axis. (b) Young's modulus of elasticity obtained from compression tests in 22 cylindrical specimens from the lumbar vertebral bodies of 16 human subjects aged 24–86 years, plotted as a function of R_2' for the water protons in the intertrabecular spaces ($r=0.91$, $p<0.0001$). (Modified from Chung et al.²⁹)

Figure 3(b). From these data, it is inferred that a global measurement of R_2' in trabecular bone is able to predict the compressive strength of this highly complicated structure. Subsequently, Jergas et al. evaluated the ability of R_2^* to predict the elastic modulus for uniaxial loading in specimens of the human proximal tibia.³⁰ They found correlations ranging from 0.87 to 0.95 in specimens in which the marrow was removed, but much weaker associations in another set of specimens where the measurements were conducted with the bone marrow intact.

5 IN VIVO QUANTITATIVE NMR OF TRABECULAR BONE

5.1 Measurement and Data Analysis

Bone marrow has cellular (hematopoietic) and fatty components, with the relative fractions varying widely, depending on anatomical site and age. The major chemical constituents of the two types of marrow are water and fatty acid triglycerides. This chemical heterogeneity of bone marrow complicates in vivo measurement of T_2^* . A linewidth measurement by means of image-guided localized spectroscopy has the advantage of providing T_2^* for each spectral component.^{31,32} Schick, in an excellent review on bone marrow NMR in vivo, described the potential of localized spectroscopy as a means to probe osteoporosis in the calcaneus, showing dramatic reductions in the linewidth of the CH_2 lipid resonance in response to trabecular bone loss.³²

Image-based (nonspectrally resolved) techniques, typically conducted by means of gradient echo³³ or asymmetric spin echo techniques,³⁴ have the advantage of providing information at multiple skeletal locations rapidly, allowing generation of maps of R_2^* ³⁵ or R_2' .³⁶ By collecting an array of images with incrementally stepped time for inhomogeneity dephasing (gradient echo delay or echo offset), the pixel amplitudes can be fitted to some model for signal decay. These methods are less sensitive to magnetic field inhomogeneity arising from effects unrelated to susceptibility-induced gradients, since the field across an imaging voxel of a few cubic millimeters is, in general, quite homogeneous.

The presence of multiple chemically shifted constituents causes an amplitude modulation that has the characteristics of an interferogram. The latter can be expressed as the modulus of the vector sum of the individual phase-modulated spectral components:^{33,37}

$$I(t) = \left| \sum_{i=1}^n I_i \right| = \left[\sum_{i=1}^n \sum_{j=1}^n I_{0i} e^{-t/T_{2i}^*} I_{0j} e^{-t/T_{2j}^*} \cos(\Delta\omega_{ij}t) \right]^{1/2} \quad (8)$$

where I_{0i} is the initial amplitude of the i th chemically shifted constituent, $\Delta\omega_{ij}$ is the chemical shift difference in rad s^{-1} between nuclei i and j , t is the dephasing time (e.g., the echo time TE in a gradient echo), and the summation is over all spectral components n . Typically, the most abundant spectral components are those of the CH_2 protons of fatty acids and of water, which are separated by chemical shift (δ) = 3.35 ppm. It has been shown that $I(t)$ can be fitted to a two-component interferogram with T_2^* and fat and water signal amplitudes as adjustable parameters and assuming $T_{2,\text{fat}}^* \approx T_{2,\text{water}}^*$.³³

Multiparameter curve fits are hampered by the difficulty of locating the global minimum, and require a relatively large number of images. One alternative is to suppress one spectral component,³⁵ which sacrifices some of the signal-to-noise ratio and is relatively sensitive to global magnetic field inhomogeneity, demanding that the field across the sample volume vary less than the chemical shift. Another approach to suppress the modulation is to sample the interferogram at the modulation frequency, ideally in such a manner that the two components are in phase with one another.³⁸ This condition is satisfied for sampling at multiples of the modulation period $T = 2\pi/\gamma\delta H_0$, which is 4.65 ms at 1.5 T field strength.

Figure 4 (a) First of a series of eight coronal gradient echo images for simultaneous measurement of T_2^* in the hip and lumbar spine, obtained by collecting 128 data samples every 4.65 ms, from a single gradient echo train so as effectively to demodulate the signal (see text for details). (b) Plot of signal measured in the trochanter [see region indicated in (a)] versus echo time, obtained from five successive scans. Solid lines are linear least-square fits, affording $T_2^* = 12.55 \pm 0.38$ ms

Another approach consists of deconvolving the amplitude-modulated signal with a reference signal.³⁹ If the marrow composition is known (e.g., all fatty, such as in most of the appendicular skeleton), the reference signal could be derived from subcutaneous fat or marrow in the diaphysis, locations where no line broadening occurs. In the time domain, deconvolution can be achieved by simple division of the marrow signal at the location of interest (trabecular bone marrow) by the reference signal, resulting in a demodulated signal that fits to a decaying exponential of rate constant R_2' . Difficulties of this approach lie in the uncertainties of the marrow composition and large-scale static field inhomogeneities, which may differ at the region of interest and the reference region.

Rather than computing T_2^* by fitting the mean signal from a two-dimensional array of pixels (often called the 'region of interest'), it is desirable to perform this calculation pixel by pixel for the generation of T_2^* maps. This, however, requires that misregistration be minimal between acquisitions, which may, for example, be achieved with a multiple echo pulse sequence that collects gradient echoes of the same polarity at multiples of the chemical shift modulation period. The precision achievable in vivo with this technique is illustrated with the data obtained from five separate scans in the same test subject in Figure 4. The data also show that chemical shift modulation is completely suppressed and that the decay is exponential to a high degree (Figure 4b). Excellent precision was also reported by Funke et al., who used a 16-echo gradient echo pulse sequence to give a coefficient of variation of 2.5% from 11 successive scans, which included repositioning following each scan.⁴⁰

Since variations in R_2 (for example from variations in marrow composition) could mask effects resulting from changes in trabecular architecture or density, a direct measurement of R_2' would be preferable. The asymmetric echo technique^{34,35} measures R_2' but is inherently inefficient as it requires separate image acquisitions for each time increment. Recently, Ma and Wehrli reported a new multislice pulse sequence capable of measuring both R_2' and R_2 in a single scan.³⁶ The method, termed GESFIDE (gradient echo sampling of FID and echo), is based on sampling the descending and ascending portion of a Hahn echo with a train of gradient echoes. The transient signal before and after the phase-reversal rf pulse decays with rate constants $R_2^* = R_2 + R_2'$ and $R_2^- = R_2 - R_2'$, respectively. If, further, the time interval between successive gradient echoes is set equal to the fat-water chemical shift modulation period (see above), R_2^* and R_2^- can be determined by curve fitting and R_2 and R_2' determined algebraically. Salient features of the method are its insensitivity to rf pulse imperfections, as well as its high precision and efficiency. Figure 5 shows the evolution of the GESFIDE signal in a region where $R_2' > R_2$, along with a computed R_2' parameter image.

5.2 Dependence of R_2^* and R_2' on Image Voxel Size and Field Strength

For a perturber that is smaller than the imaging voxel but much larger than the molecular scale (also referred to as 'mesoscopic' scale⁴¹) the susceptibility-induced line broadening should be independent of image voxel size. However, if the

Figure 5 The GESFIDE method. (a) Evolution of the gradient echo signal from the region of interest in the greater trochanter before and after the phase-reversal rf pulse (S , signal; points obtained from five successive scans). Prior to the phase-reversal pulse, the signal evolves with a time constant $R_2^* = R_2 + R_2'$, subsequently with $R_2^- = R_2 + R_2'$. The change in the sign of the slope indicates that $R_2' \gg R_2$. (b) Computed R_2' map. Note the high intensity for structures pertaining to trabecular bone, consistent with enhanced R_2' as a result of susceptibility-induced line broadening. (Modified from Ma and Wehrli³⁶)

voxel size decreases below the typical range of gradients induced by the field perturbing trabeculae, then the likelihood of this voxel falling in a region sufficiently removed from the field gradients induced by trabeculae increases. As a consequence, the mean T_2' is expected to increase with decreasing pixel size. Majumdar and Genant studied this effect in trabecular bone of various densities.³⁵ They found that the T_2' histogram becomes wider and more asymmetric with decreasing pixel size. However, if the voxel size is large relative to the range of the gradients, the value of T_2' becomes independent of voxel size, which is the case for pixels on the order of 1.5–2 mm. The distribution of T_2' as a function of image resolution is shown in Figure 6.

The induced magnetic field is proportional to the polarizing static field. In the absence of diffusion (static dephasing regime) one would, therefore, expect a linear relationship between trabecular bone marrow R_2' and field strength. Parizel et al. reported the field strength dependence of R_2^* from measurement of the gradient echo signal decay at 1.5, 1.0, and 0.2 T in vertebral bone marrow in a single volunteer⁴² and found R_2^* to increase with field strength. More recently, Song et al. performed a detailed study of the field strength dependence of R_2 and R_2' in the calcaneus at 1.5 and 4 T by means of the GESFIDE technique.⁴³ They found R_2' to scale nearly proportionally with field strength while R_2 was almost field-strength invariant. The data, which show that at 4 T R_2' accounts for nearly 90% of the total relaxation rate ($R_2^* = R_2 + R_2'$), are summarized in Table 1.

5.3 Clinical Studies in Patients with Osteoporosis

The most likely association involving R_2^* is with bone marrow density (BMD). In fact, the theory developed by

Figure 6 Smoothed T_2' histograms obtained from T_2' maps computed from axial images in the epiphysis of the distal femur, a site of dense trabeculation. As image resolution increases (smaller pixel size), the histogram broadens and becomes skewed. Means are found to vary between 41.7 ms at 0.32 mm pixels size and 25.7 ms at 1.25 mm pixel size. (Modified, with permission, from Majumdar and Genant³⁵)

4.0	19.2 $\pm$ 3.4	178.4 $\pm$ 37.6

^aSD, standard deviation from values for five subjects. R_2' (at 4 T)/ R_2' (at 1.5 T) = 2.73. Source: Song et al.⁴³

Yablonskiy and Haacke predicts a linear relationship between R_2' and the volume fraction of the perturber.²⁵ A possible relationship between these parameters was suggested by the observed T_2^* shortening in the distal femur from the diaphysis (lowest trabeculation) toward the metaphysis and epiphysis of the bone (highest trabeculation).³¹ Majumdar et al. determined R_2' in intact specimens of human vertebral trabecular bone after bone marrow removal and suspending the bone in saline.⁴⁴ The measurements afforded a linear correlation between R_2' and BMD (in $mg\ cm^{-3}$), obtained from QCT, with a slope of $0.20 \pm 0.02\ s^{-1}\ mg^{-1}\ cm^3$ ($r = 0.92$). The same group extended these studies in vivo in normal volunteers to the distal radius and proximal tibia.³⁵ Confirming earlier work, they found both BMD and R_2' to depend on the anatomical site of measurement. In excellent agreement with in vitro data, they measured $0.20 \pm 0.01\ s^{-1}\ mg^{-1}\ cm^3$ ($r = 0.88$) for the combined data from both anatomic sites.

Since inception of the T_2^* method, several groups have evaluated its potential for assessing osteoporosis and have compared it with other modalities, notably DEXA and QCT.^{33,40,45–47}

An early pilot study on a small group of patients with clinically established osteoporosis of the spine ($n = 12$) and an equal number of control subjects showed the former to have significantly prolonged bone marrow T_2^* in lumbar vertebra L5.³³ A larger follow-up study was designed to explore whether image-based measurements of T_2^* could provide an index of the integrity of trabecular bone as a possible criterion for predicting fracture risk. The value of R_2^* was measured in 146 non-black women at 1.5 T field strength by means of five successive gradient echoes, spaced 4.6 ms apart to minimize fat–water chemical shift modulation. Data were fitted to an exponential model and data sets with $p > 0.05$ for the Pearson correlation rejected. The control population ($n = 77$, mean age 46.6 ± 14.9 years) consisted of women with mean spinal BMD $> 0.9\ g\ cm^{-2}$ (DEXA) or $> 90\ mg\ cm^{-3}$ (QCT), and no vertebral deformities. The patient population ($n = 59$; mean age 59.7 ± 10.2 years) was made up of women with osteoporosis of the spine, exhibiting at least one radiographic deformity of the thoracic vertebrae and/or BMD below the cutoff for controls. The extent of deformity was determined as a mean deformity index, DI_{av} . The value of R_2^* was significantly lower in osteoporosis for all L vertebrae ($p < 0.001$), except for L1. The best discriminator was the average of L3–L5 ($R_{2,av}^*$) for which means and standard errors obtained were $64.8 \pm 1.2\ s^{-1}$ and $53.4 \pm 1.2\ s^{-1}$ in controls and osteoporotics, respectively ($p < 0.0001$). Both R_2^* and BMD correlated with DI_{av} , the correlation with R_2^* being slightly stronger ($r = 0.40$; $p < 0.0005$, versus $r = 0.36$; $p < 0.001$). Finally, $R_{2,av}^*$ was significantly cor-

related with mean BMD ($r = 0.54$; $p < 0.0001$, slope = $31.4\ s^{-1}\ g\ cm^{-2}$, $p < 0.0001$).

Overall, these findings corroborate the results of the prior study in that subjects with osteoporosis have lower R_2^* values of their vertebral marrow and show that MR may have the potential to distinguish patients with fractures from those without this condition. Nevertheless, the results fell short of demonstrating MRI's superiority over bone densitometry.

A more recent study from the same laboratory, undertaken with more advanced methodology, involving measurements of R_2' (rather than R_2^*) at multiple skeletal sites, indicates the complementary nature of this parameter to BMD.⁴⁸ In this work, the rate constants R_2' and R_2 and the marrow fat fraction were measured in the lumbar vertebrae and proximal femur by the GESFIDE method.³⁶ Sixteen gradient echoes were collected, eight each before and after the phase-reversal pulse, at TE 4.6, 6.9, 9.2, 11.5, 13.8, 18.4, 23.0, and 27.6 ms at 57.0, 61.6, 66.2, 70.8, 73.1, 75.4, 77.7, and 80 ms, the latter being an rf echo. Fat and water signal amplitudes were computed from echoes 1–3 by three-point Dixon processing,⁴⁹ and from these, the volume fractions of the two constituents. The value of R_2' was moderately (positively) correlated with BMD at all sites ($r = 0.46$ – 0.69 ; $p < 0.0001$), albeit with different slopes, indicative of the different trabecular orientation relative to the static field at the various anatomical locations. For example, in the femoral neck, the slope was twice that found for the average R_2' from lumbar vertebrae 2–4 ($38.0\ s^{-1}\ g\ cm^{-2}$ versus $19.2\ s^{-1}\ g\ cm^{-2}$). The value of R_2' classified the subjects well at all sites, but the strength of the discrimination was greater at the femoral sites, a finding that agrees with a small patient study by Machann et al.,⁵⁰ and suggests that skeletal sites rich in yellow marrow (such as the calcaneus) are better predictors of osteoporosis than measurements in the vertebrae. This observation can be understood when the different susceptibilities of fat (i.e., yellow marrow) and water (i.e., hematopoietic marrow) are considered. It is well known that fat is less diamagnetic than water (see, for example, Hopkins and Wehrli¹⁸) thus resulting in a greater absolute susceptibility difference $\Delta\chi$ between bone and bone marrow, which increases the sensitivity of R_2' to variations in bone volume fraction [Equation (7)]. In fact, when the spine R_2' values are normalized by correcting for varying bone marrow composition, achieved by computing R_2' as it would be observed for an all yellow marrow composition, the slope of the R_2' versus BMD correlation increased from 19.2 to $28.4\ s^{-1}\ g\ cm^{-2}$.

Finally, the value of R_2' in this study was found to be predictive of vertebral fracture status. The latter was defined by measuring vertebral deformities in the thoracic and lumbar spine in terms of standard deviations from normalcy and by selecting a threshold beyond which a fracture was considered present. When only a single parameter was included in the logistic regression, DEXA BMD was found to predict fracture status better than R_2' , with Ward's triangle exhibiting the strongest correlation ($r^2 = 0.48$). Further, the femoral sites were more predictive than the lumbar spine, a finding that applies to both R_2' and BMD. However, combining MR and BMD significantly improved prediction. The strongest association was found for the combination of R_2' measured in the greater trochanter and BMD at the Ward's triangle, affording a 30% increase in the strength of the correlation relative to BMD alone ($r^2 = 0.62$). By contrast, the combination of multiple

Figure 7 Images at microscopic dimension showing trabecular structure: (a)–(c) orthogonal views obtained from a 64^3 array of 3D spin echo array of images acquired at 9.4 T on a specimen of trabecular bone from bovine tibia ($114\ \mu\text{m} \times 114\ \mu\text{m} \times 139\ \mu\text{m}$ voxel size); (a) transverse and (b), (c) longitudinal sections. Note the preferential orientation of the trabeculae along the inferior–superior direction. (d) Shaded surface display of the same array of data, resolution-enhanced by means of a subvoxel tissue classification technique using Bayesian segmentation⁶⁰

BMD sites did not yield stronger associations. These data are promising in that they underscore the complementary nature of R_2' and the potential role of structure in affecting the trabecular bone's mechanical competence.

6 HIGH-RESOLUTION IMAGING OF TRABECULAR BONE STRUCTURE

6.1 In Vitro Cancellous Bone NMR Microscopy

Whereas the measurement of the induced magnetic field inhomogeneity provides structural information indirectly, high-resolution MRI at microscopic dimensions has the potential for nondestructive mapping of three-dimensional trabecular morphology, as an alternative to conventional microscopy from sections⁵¹ or tomographic X-ray microscopy.^{52–54} Bone is well suited for imaging by NMR since it appears with background intensity and, therefore, provides excellent contrast with marrow, which has high signal intensity. Ideally, the image voxel size is smaller than a typical structural element (i.e., a trabecula), in which case partial volume blurring is minimal and the resulting histogram is bimodal, allowing segmentation (generation of a binary image) by setting the intensity threshold midway between the marrow peak and background. Clearly, the voxel size needed to satisfy this requirement depends on the trabecular width, which is species dependent. Bovine trabeculae are 200–300 μm thick, those in humans between 100 and 200 μm , whereas the trabecular thickness in rats is only 50–70 μm , consequently demanding considerably higher resolution.

Most of the work reported so far has been conducted on small-bore microimaging systems at 300 or 400 MHz proton

resonance in human cadaver or biopsy specimens^{55–58} or animals, at resolutions ranging from 25 to 120 μm . Ex vivo, the quality of the images is optimized by substituting the marrow with gadolinium-doped water as a means to optimize the signal-to-noise ratio. The background gradients from the susceptibility-induced fields can cause artifacts in the form of signal loss from intravoxel phase dispersion [Equation (1)]. Since these phase losses are recoverable—assuming diffusion to be negligible—spin echo detection is advantageous. Alternatively, the dephasing time should be minimal; this can, for example, be achieved with projection–reconstruction techniques, as applied in microimaging of lung parenchyma.⁵⁹

At marginal resolution the accuracy of the 3D structures derived from NMR images can be improved with such techniques as subvoxel tissue classification.⁶⁰ Based on a statistical model for the noise and partial volume averaging, the number of subvoxels containing marrow can be determined and the most likely spatial arrangement ascertained using probabilistic arguments for the interaction between adjacent subvoxels. Chung et al. developed algorithms for the measurement of the structural parameters of interest (bone volume fraction, mean trabecular thickness, and mean trabecular plate separation⁵⁵ based on two-dimensional images. These techniques, however, are merely the digital imaging adaptations of stereology, the methodology practiced by the histomorphometrist who performs measurements on anatomic sections which are then extrapolated to the third dimension.⁶¹ However, trabecular bone is inherently three-dimensional and anisotropic. Figure 7 shows three orthogonal images from bovine trabecular bone illustrating the bone's anisotropic structure, along with a surface projection image enhanced by subvoxel classification.⁶⁰

6.2 Relationship between Architecture and Strength

Knowledge of the three-dimensional architecture of cancellous bone allows one of the key questions to be addressed, i.e., whether structure is predictive of the bone's strength. While still controversial, it is known that apparent density (essentially bone volume fraction, i.e., the amount of bone present per unit volume) predicts anywhere from 40–80% of Young's modulus (and thus ultimate strength); the remainder is generally attributed to architecture.⁶²

To investigate whether architecture is predictive of the modulus of elasticity for compressive loading, Hwang et al. acquired three-dimensional images at 78 μm isotropic resolution of cadaver specimens cored from the ultradistal radius, after the cores were tested nondestructively in compression along the bone's anatomic axis. Rather than segmenting the images, bone volume fraction (BVF) images were generated by fitting the histogram to a two-peaked noiseless histogram convolved with Rician noise, using maximum likelihood methods. In this manner the true BVF can be found for each pixel as the probability of finding bone at that location. This idea was then extended to two-point probabilities, for example the probability of finding bone at two neighboring locations x_i and x_{i+n} along a row of voxels, $P(x_i, x_{i+n}) = \text{BVF}(x_i)\text{BVF}(x_{i+n})$. Averaging the two-point probabilities over all locations yields the spatial autocorrelation function (AFC). Because of the quasiregular nature of the trabecular lattice, the AFC has a maximum at the average spacing between trabeculae along that direction. This concept can be extended and other parameters characterizing

	Male 76 years	Male 80 years	Male 53 years
Bone volume fraction	0.16	0.14	0.12
Young's modulus (MPa)	316	676	543
Transverse			
Longitudinal			
Three-dimensional			

Figure 8 NMR images of three samples of trabecular bone illustrating its structural variability. Note that the sample from the 76-year-old man has the lowest modulus in spite of having the highest bone volume fraction. However, the bone of the 80- and 50-year-old donors is considerably more tubular, which explains their greater Young's modulus.

the trabecular network defined. One useful parameter is tubularity, which quantifies how 'tubular' the bone is along its anatomic axis, which is the direction along the radius (z). Tubularity is given as $AFC_z(1)/AFC(0)$, where $AFC_z(1)$ is the average of the product of BVF in corresponding voxels of successive slices. The significance of this parameter in determining cancellous bone strength is illustrated with Figure 8 showing cross-sectional and projection images of three radius specimens of varying BVF. It is noteworthy that the specimen with the highest BVF is only half as strong as the two other specimens that are both more tubular. A detailed analysis on specimens from 23 cadavers of widely varying BVF, tubularity, and longitudinal spacing (spacing between trabeculae orthogonal to the direction of loading) jointly best predicted Young's modulus, accounting for over 90% of its variance (as opposed to BVF, which explained only 50%). Clearly, a perfectly tubular structure could not fail by loading in the direction of these trabeculae. However, as the deviation from such an ideal geometry decreases, the transverse trabeculae, acting as cross-ties, become increasingly important.

6.3 In Vivo Microimaging

In vivo imaging of the microarchitecture of cancellous bone at voxel sizes sufficient to resolve individual trabeculae is considerably more challenging than measurements on small

specimens in vitro. The main difficulty is to achieve sufficient signal to noise ratio in scan times tolerated by the patient, typically on the order of 10 min. A second problem is subject movement, which, even on a minute scale on the order of a pixel (100–200 μm), can cause blurring and artifacts, precluding derivation of accurate structural parameters. Restraining the portion of the body being scanned is usually not sufficient to prevent motion blurring. However, the incorporation of navigator echoes into the pulse sequence proves to be effective.⁶³ Additional echoes, which are not phase-encoded, generate projections of the object from which the displacement can be measured and a commensurate phase correction applied to the k -space data. The effect of alternate navigator echoes incorporated into a three-dimensional spin echo sequence was found to eliminate motion degradation effectively (Figure 9).⁴³

The third problem is the considerably lower resolution achievable in vivo, which, while sufficient to visualize the trabecular architecture, demands more sophisticated methods for image restoration and analysis. In spite of these difficulties, a growing body of literature has accumulated during the past few years, highlights the potential of in vivo micro-MRI to probe bone structure.^{64–68}

The image voxel sizes reported for cancellous bone imaging in humans range from $2 \times 10^{-5} \text{ mm}^3$ in the distal phalanx of the middle finger⁶⁹ to $2 \times 10^{-2} \text{ mm}^3$ in the calcaneus.⁶⁸ At these resolutions, the histogram is monomodal (instead of

Figure 9 (a) FLASE (fast large-angle spin echo) sequence with navigator echoes alternating between frequency and phase-encoding axes ($137 \mu\text{m}^3 \times 137 \mu\text{m}^3 \times 350 \mu\text{m}^3$ voxel size). The zeroeth moment of all three gradients is nulled before the navigators are acquired. Also, to maintain steady state, the navigator gradients are refocused after collecting motion data. (b) Image of the distal radius from a 56-year-old female at this voxel size, before motion correction. (c) Image after motion correction. (With permission from Song et al.⁴³)

bimodal as it is at higher resolution) and, therefore, does not provide simple criteria for segmenting the images into bone and bone marrow. The limitations imposed by marginal resolution to segment the images and derive structural parameters by image processing has been addressed in various ways. Majumdar et al. set the threshold at half the peak maximum (observed for cortical bone) in the grayscale-inverted histogram.⁶⁵ In recent work on the calcaneus, Link et al. compared structural measures in postmenopausal subjects who had suffered hip fractures with those in age-matched controls.⁶⁸ They found that both apparent trabecular bone volume and apparent trabecular separation were stronger predictors of hip fracture than BMD of the proximal femur. Gordon et al. applied an adaptive threshold to eliminate errors from intensity variations caused by the inhomogeneous reception profile of the surface coil, by thresholding the image against the low-pass filtered version of itself, followed by a second threshold at 50% of the maximum.⁶⁶ From the threshold and subsequent skeleton images they determined hole size and a connectivity index and

found these parameters to be correlated with subject age (positively and negatively).

Whereas the above methods cannot retrieve the true BVF, they, nevertheless, can provide parameters that can effectively characterize the trabecular network and provide clinically relevant information. True BVF images have been obtained in vivo in the distal radius by means of a histogram deconvolution technique.⁷⁰ In brief, a model histogram is convolved with Rician noise (the type of noise encountered in magnitude NMR images⁷¹) and the result compared with the observed histogram. The resulting error then serves as input to improve the noiseless histogram, and the process is repeated until the error falls below a predetermined level. Finally, the actual noiseless image is computed using both intensity and connectivity arguments. Wehrli et al. obtained BVF images in this manner in the distal radius of a small cohort of patients with and without vertebral fractures.⁶⁷ The parameters that proved to be successful in predicting the elastic modulus in vitro were also evaluated to explore whether architecture is associated with the

degree of vertebral deformities, measured in terms of a fracture index, D_{fract} . Whereas none of the individual structural measures was found to correlate with the D_{fract} , a highly significant relationship ($R=0.78$; $p=0.0016$) was found between D_{fract} and a function of tubularity and longitudinal spacing. These data further emphasize the role of architecture in determining trabecular bone's resistance to fracture, and highlight the prospects of in vitro micro-MRI as a noninvasive modality to assess trabecular microstructure.

Biographical Sketch

Felix W. Wehrli. b 1941. M.S., 1967, Ph.D., 1970, chemistry, Swiss Federal Institute of Technology, Switzerland. NMR application scientist, Varian AG, 1970–79; Executive Vice President, Bruker Instruments, Billerica, 1979–82; NMR Application Manager, General Electric Medical Systems, Milwaukee, 1982–88. Currently Professor of Radiologic Science and Biophysics, University of Pennsylvania Medical School. Editor-in-Chief of *Magnetic Resonance in Medicine* 1991–present. Over 100 publications. Current research specialty: NMR imaging of connective tissues, biomaterials, specifically trabecular bone.

MRI of Musculoskeletal Neoplasms

Johan L. Bloem

Leiden University Medical Center, The Netherlands

1 INTRODUCTION

Staging of disease is the single most important reason for performing MRI in patients with musculoskeletal tumors. Other indications for MRI in these patients are detection, specific diagnosis, chemotherapy monitoring, and detection of recurrence. The last two indications are becoming increasingly important. After a short discussion about technique, this article deals with clinical applications of MRI in patients with primary musculoskeletal tumors, tumor-like lesions and metastases.

2 TECHNIQUE

When a bone lesion is potentially malignant, imaging studies (to allow local staging) and biopsy are needed. Imaging studies are performed prior to histologic biopsy, because they can be used to plan the biopsy procedure. Furthermore, biopsy induces reactive changes (edema, hemorrhage), which interfere with accuracy of staging. Cytologic biopsy is a minimally invasive procedure that can be useful in soft tissue tumors, prior to MRI, to differentiate between broad categories such as lymphoma or sarcoma metastasis. Conventional radiographs have to be present when MRI is planned and executed. This should be a golden rule and will avoid both major disasters and silly mistakes.

High- or low-frequency (low or high field) magnetic resonance (MR) systems can be used for imaging musculoskeletal tumors. It is possible to stage bone tumors accurately at 0.5 T. Whenever possible, dedicated coils should be used in order to increase spatial resolution. It is important to use both T_1 - and T_2 -weighted sequences.

T_1 -weighted sequences are used for intramedullary staging and T_2 -weighted sequences are used for defining soft tissue extension and cortical involvement. A large number of pulse sequences, such as STIR (short τ inversion–recovery), gradient echo (GE) imaging, fast or turbo spin echo (TSE), chemical shift imaging, magnetization transfer contrast added to various pulse sequences, etc., are available. For imaging of musculoskeletal tumors, conventional spin echo or TSE sequences are best used to obtain T_1 -weighted images. For T_2 -weighting conventional spin echo sequences, or preferably TSE sequences, are used. Contrast between tumor and normal tissue, especially fat containing tissue, is greatly enhanced by combining TSE with fat selective presaturation. It is important to make sure that enough T_2 weighting is achieved. At 0.5 T, a TSE sequence with a TR of 3000–4000 ms and an effective TE of 150 ms has proven to be as good as the conventional T_2 -weighted spin echo sequences in our practice. When fat sup-

pression is used, the TE should be shortened. Contrast between tumor and muscle on T_2 -weighted SE or TSE images is superior to that on native T_2^* -proton density weighted, or enhanced GE images. STIR–TSE sequences are very sensitive, but the specificity and low signal-to-noise ratio are low. When T_1 or T_2 -weighted images are mentioned in this article, I refer to both conventional spin echo and TSE sequences.

Routinely, multiple imaging planes are used: the transverse plane (T_2 -weighted) for soft tissue extension, and sagittal or coronal planes (T_1 -weighted) for intraosseous extension (Figure 1). The sagittal and coronal planes can be angulated to be parallel to the long bones. Additional planes are used when necessary, for instance the transverse plane for intraosseous staging to rule out partial volume effects of cortical bone which may occur in the sagittal and coronal plane in thin tubular bones in children. Slice thickness varies between 2 and 10 mm and the number of excitations will be 1–4, depending on various parameters such as slice thickness, TR , TE , type of coil, and field strength used. Echo train length will vary between 3 and 8.

Gadolinium enhanced studies are performed following intravenous injection of 0.1–0.2 mmol Gd chelate/kg body weight with a T_1 spin echo or TSE technique and dynamic magnetization prepared GE imaging. The T_1 -weighted sequences are combined with fat selective presaturation. It is not advisable to combine STIR sequences with gadolinium, since suppression of signal from enhancing tissue is possible. Out-of-phase GE images may further enhance contrast as compared with in-phase GE images.

Gadolinium can be used in patients with poor renal function, and can be removed from the body with dialysis.

3 MRI CHARACTERISTICS

Bone marrow and fat exhibit a high signal intensity (white) on T_1 -weighted sequences, whereas cortex, fibrous cartilage, and ligaments are seen as signal void (black) structures. Hyaline cartilage and muscle have an intermediate signal intensity (gray). Relative signal intensities of muscle, fat, and bone marrow decrease somewhat on T_2 -weighted spin echo sequences. This is in contrast to the increase of signal intensity of structures containing a large amount of water, such as hyaline cartilage. Fat displays a high signal intensity on TSE images.

Distribution of areas with abnormal signal intensity is important, not only for differentiating tumors and tumor-like lesions, but also in identifying normal variants. The low to intermediate signal intensity areas of red bone marrow in the axial skeleton and femur diaphysis in adults and also in the periphery of the skeleton in adolescents and children on T_1 -weighted images may be confusing.¹ On STIR sequences, the high signal intensity of red marrow is easily differentiated from the absence of signal from the nulled yellow marrow. Low signal intensity areas within bone marrow on GE images are due to susceptibility effects secondary to the presence of bone trabeculae and cortex, and iron in red bone marrow.

Like most pathologic tissues, musculoskeletal tumors usually have prolonged T_1 and T_2 relaxation times (Figure 1). Therefore, osteolytic tumors have a relatively high signal intensity on T_2 -weighted images and a relatively low signal intensity on T_1 -weighted images. Because of their low spin

Figure 1 Osteosarcoma in an 18-year-old male imaged with a 0.5 T MRI system. (a) Coronal T_1 -weighted (600/20) MR image displays the intraosseous tumor margins very well. Medial soft tissue extension and periosteal reaction are also depicted. The tumor has an inhomogeneous low to intermediate signal intensity. (b) Axial T_2 -weighted TSE (3570/150) MR image. Contrast between the high signal intensity of viable tumor and the low signal intensity of muscle is excellent. However, both tumor and fat have a similar high signal intensity. Ossified periosteal reaction and ossified tumor display a signal void

density and short T_2 relaxation time, osteosclerotic components or calcifications within the tumor have a low signal intensity on both T_1 - and T_2 -weighted images. Small calcifications detected by plain radiographs or computerized tomography (CT) often cannot be detected by MRI. Liquefaction or lacunae caused by necrosis within a tumor can often be identified because the T_1 and T_2 relaxation times are even longer than those of viable tumor.

Cortical bone and periosteal reaction can be evaluated not only with CT, but also with MRI. Normal cortical bone is represented as a signal void area, whereas intracortical lesions almost invariably show areas of increased signal intensity relative to cortex, on T_1 -weighted, gadolinium enhanced and T_2 -weighted images. Likewise, mineralized periosteal reaction is seen as a solid or layered signal void area, whereas the nonmineralized cellular cambium layer of the periosteum has a high signal intensity on T_2 -weighted images.

Only in selected cases does MRI allow a specific diagnosis to be made. The inhomogeneity of the tumor consisting of viable tumor with different histologic components, necrosis, hemorrhage, and reactive changes make it impossible to differentiate histologic types by relaxation times. MRI increases

specificity only when unusual features such as high signal intensity on T_1 -weighted images, low signal intensity on T_2 -weighted images, or specific morphology or enhancement patterns are observed. Examples of lesions with a high signal intensity on T_1 -weighted sequences are fat and subacute (one week to several months old) hematoma. The signal intensity of hematoma depends on the sequential degradation of hemoglobin, cell lysis, and field strength of the MR system.² The high signal intensity representing methemoglobin is initially seen in the periphery, and subsequently extends towards the center of the hematoma. Interstitial hemorrhage is more diffuse than hematoma and is accompanied by edema resulting in aspecific prolonged T_1 and T_2 relaxation times, irrespective of age.

Although hemorrhage and hematoma may occur in any tumor or hemophilic pseudotumor, telangiectatic osteosarcoma and aneurysmal bone cyst are the lesions to consider when hemorrhage is found.³ Telangiectatic osteosarcoma will display malignant features such as indistinct margins and inhomogeneity, whereas aneurysmal bone cyst often contains multiple compartments and displays well-defined margins. Layering or a fluid level, as can be demonstrated with MRI, is more often

Figure 2 Hemangioma in the adductor compartment of the left thigh imaged with a 1.5 T MRI system. (a) The high signal intensity and morphology on this axial T_1 -weighted (600/20) spin echo image are typical of hemangioma. A soft tissue sarcoma would occupy more space. (b) After intravenous administration of 0.1 mmol Gd-DTPA/kg body weight, diffuse enhancement resulting in an increase in signal intensity is appreciated. This is consistent with the presence of well-vascularized cellular tissue. (c) On the coronal T_1 -weighted (600/20) spin echo image, the same features are visualized. The signal void of rapid flow within the hemangioma is shown to best advantage

seen in aneurysmal bone cyst than in telangiectatic osteosarcoma. These fluid levels may also be encountered in chondroblastoma, giant cell tumor, especially when a secondary aneurysmal bone cyst is present, and occasionally in other tumors as well.³ Another reason for hematoma is surgical intervention. Since hematoma and edema may be quite extensive following histological needle or open biopsy, imaging studies are preferably performed prior to invasive procedures.

High signal intensity may also be encountered in lipoma. On T_2 -weighted images the signal intensity will remain identical to that of subcutaneous fat. Liposarcomas may contain areas consisting of well-differentiated fat; these areas have the same appearance on MRI as benign lipomas. Liposarcomas, however, invariably contain large areas (myxoid liposarcoma) or some areas (lipoblastic liposarcoma) of poorly differentiated fat and mesenchymal tissue, which have the same MRI characteristics as other high-grade malignancies.

The signal intensity of hemangioma and arteriovenous malformations is variable. The signal intensity may be high on T_1 -weighted sequences due to adipose tissue within the lesion and due to slow flow through dilated sinuses and vessels (Figure 2). Because of slow flow, the serpiginous vascular channels typically display a high signal intensity on T_2 -weighted images. Signal void represents high flow in vascular channels. Fat predominates in asymptomatic vertebral hemangiomas. Vascularity is often more pronounced in symptomatic hemangiomas.⁴

A low signal intensity on T_2 -weighted sequences, secondary to a low spin density and/or short T_2 relaxation time, may indicate the presence of calcification, osteoid, collagen, fibrosis, hemosiderin, or bone cement. Low signal intensity areas on T_2 -weighted images may be present in pigmented villonodular synovitis, giant cell tumor of tendon sheath, elastofibroma, fibromatosis, fibrous dysplasia, neuroma (Morton neuroma), etc.³ The signal intensity reflects the amount of collagen and

fibrous tissue present. Cellular areas will be seen as high signal intensity areas on T_2 -weighted images, whereas the paucicellular areas will exhibit a low signal intensity on all pulse sequences.

Low signal intensity masses located within ligaments (Achilles tendon) representing xanthomas may be encountered in patients suffering from familial hypercholesterolemia. This is caused by deposition of cholesterol in combination with dense collagen fibers.

The flow void phenomenon, representing rapid flow in vascular channels, such as found in arteriovenous malformations, may also be a cause for low signal intensity on T_2 -weighted images. This is in contrast to the characteristics of cavernous or capillary hemangioma.

The morphology, distribution, and localization of disorders can also be used in MRI to characterize a lesion. Indistinct margins, a soft tissue lesion with size larger than 3 cm, and heterogeneity indicate malignancy, whereas well-defined margins and homogeneity are more indicative of a benign lesion.^{3,5} Of course there are exceptions to these general statements. Aggressive fibromatosis is a benign lesion characterized by infiltrative growth and a very high recurrence rate. Other benign lesions such as active eosinophilic granuloma may also present with indistinct margins, just as malignant lesions may present with well-defined margins.

Edema, characterized by an increased signal intensity on T_2 -weighted images, a decreased signal intensity on T_1 -weighted images, and indistinct margins, is a poor indicator of malignancy. Extensive soft tissue and bone marrow edema is frequently encountered in osteoid osteoma, osteoblastoma, and chondroblastoma. Edema in these benign entities is often more pronounced than in malignant tumors. Peritumoral high signal intensity in the soft tissue of patients with primary malignant tumors may represent only edema or a reactive zone also containing tumor. Edema is found in and around many lesions, including eosinophilic granuloma, fracture, bone bruise, necrosis, and transient osteoporosis.³

Neurofibroma is easily recognized on both CT and MRI when it presents as the classic dumb-bell tumor of the vertebral canal. Plexiform neurofibromatosis extends along neural bundles in a lobulated fashion, and is thus also easily recognized. When located in the retroperitoneum or pelvis, these plexiform neurofibromas may be quite extensive. The signal intensity of neurofibroma is determined by its prolonged T_1 and T_2 relaxation times, low to intermediate signal intensity on T_1 -weighted images, and a very high signal intensity on T_2 -weighted images. When present, collagen and fibrous tissue decrease the signal intensity (usually centrally).

The distribution of areas with abnormal signal intensity is important, not only for differentiating between tumors and tumor-like lesions, but also for identifying normal variants. The low to intermediate signal intensity areas of red bone marrow in the axial skeleton and femur diaphysis in adults and also in the periphery of the skeleton in adolescents and children on T_1 -weighted images may be confusing.

When reviewing an MR examination, clinical data and radiographs are of paramount importance. Many tumor-like lesions, such as those due to Paget's disease, pseudoaneurysms, polymyositis, osteomyelitis, and stress fractures, can be identified in the proper clinical setting.

Osteomyelitis will, in contrast to Ewing's sarcoma, usually display only reactive changes in the surrounding soft tissue. However, a soft tissue abscess may be encountered.

Stress fractures present as irregular or band-like (perpendicular to cortical bone) areas of low signal intensity on T_1 -weighted images. The high signal intensity seen on T_2 -weighted or STIR sequences represents edema.

4 GADOLINIUM ENHANCED MRI

The pharmacokinetics of gadolinium chelates are similar to iodinated contrast agents. This paramagnetic contrast agent acts indirectly by facilitating T_1 and T_2 relaxation processes through an alteration of the local magnetic environment. Shortening of both relaxation times is a function of the concentration of the gadolinium complex. Initially, an increase in the gadolinium complex concentration results in a predominantly shortened T_1 relaxation time and an ensuing increased signal intensity on T_1 -weighted images (Figure 2). With an increasing concentration of the gadolinium complex, the signal intensity drops because of the dominant effect on the T_2^* relaxation time (dephasing). With the concentrations used in clinical practice (0.1–0.2 mmol/kg body weight for intravenous administration), the shortening of T_1 relaxation time supervenes. Only in areas where a high concentration is reached, such as in the urinary bladder or early in a dynamic sequence during bolus administration in an artery, can a signal void occur.

Well perfused, often cellular, tumor components are able to accumulate a high concentration of gadolinium, which results, through shortening of the T_1 relaxation time, in a high signal intensity on short TR/TE (600/20) images, as opposed to some tumor components, such as sclerosis, old fibrosis and liquefaction, which are not well perfused and therefore do not show a high signal intensity on the postcontrast images. In general, the presence or absence of late enhancement is not a very good indicator of malignancy. Still, gadolinium may increase tissue characterization.

Although the intravenous administration of Gd-DTPA (DTPA, diethylenetriaminepentaacetic acid) may assist in differentiating viable tumor from liquefaction and edema, neovascularity in necrotic areas may also be enhanced. Differentiation between viable and necrotic tumor is, as a consequence, not always possible. Dynamic MRI may assist in differentiating tumor from reactive tissue, since viable tumor usually enhances faster than reactive tissue. Dynamic sequences, obtained during gadolinium complex administration, with a temporal resolution of at least 3 s can be used to help to differentiate benign from malignant soft tissue tumors. Peripheral enhancement starting within 6 s after arterial enhancement without further increase in enhancement suggests malignancy.⁶

Static short TR/TE spin echo images may suggest a specific diagnosis in selected cases. Well-differentiated cartilaginous tumors containing large paucicellular cartilage fields or cartilage fields with mucoid degeneration demonstrate no or only slight enhancement. Only the margin and cellular septae in the periphery and within the tumor enhance. Because of the lobulated gross anatomy of enchondroma and low grade (grade I and II) chondrosarcoma, the postcontrast MRI scans of these tumors exhibit a septal-like or curvilinear (serpentine) enhancement pattern⁷ (Figure 3). Mature enchondromas do not

Figure 3 Chondrosarcoma grade II imaged with a 1.5 T MRI system. (a) The tumor originating from the petrous bone has an atypical low signal intensity on this axial T_1 -weighted (550/20) spin echo image. (b) The same sequence is repeated 5 min after intravenous administration of 0.1 mmol Gd-DTPA. A serpiginous enhancement pattern consistent with the presence of fibrovascular septations of well-differentiated chondrosarcoma is visualized. Compression on the temporal lobe and the brainstem is present

enhance. Enchondromas and osteochondromas may, however, enhance in the adult population 10 s or later after arrival of contrast agent in the artery. Central or peripheral chondrosarcoma grade I typically enhances within 10 s of arterial enhancement. Benign cartilaginous lesions in children or in association with sursae (mechanical stress) may also enhance early. Only high-grade cartilaginous tumors such as chondrosarcoma grade III and mesenchymal chondrosarcoma exhibit the aspecific homogeneous or inhomogeneous enhancement displayed by most tumors.

Other cartilage containing tumors such as chondroid osteosarcoma may also show areas with curvilinear enhancement. Usually other criteria such as morphology will assist in differentiating these lesions. A chondroid osteosarcoma is less homogeneous than a well-differentiated cartilaginous tumor and often contains large areas with osteoid, which can be recognized.

The curvilinear enhancement of well-differentiated cartilaginous tumors must be differentiated from thin peripheral enhancement of the pseudocapsule of lesions such as eosinophilic granuloma and solitary bone cyst.

5 LOCAL TUMOR STAGING

Adequate, wide or radical surgery has been a prerequisite for proper treatment of patients with primary malignant musculoskeletal tumors. The choice of therapy depends on a number of factors such as the grade of malignancy, the response to

neoadjuvant therapy, local tumor extension, and the presence or absence of regional or distant metastases. The surgical staging system developed by Enneking takes all these factors, with the exception of the response to neoadjuvant therapy, into account.

The biologic aggressiveness, indicated by the grade, is the key factor in the selection of the surgical margin required to achieve control. Four different surgical procedures, which imply four different margins, are recognized: intralesional, marginal, wide, and radical. The exact anatomic location of tumor is the key factor in selecting how a required tumor-free margin can be accomplished.

5.1 Bone Marrow Involvement

For extremities, a plane through the long axis of a long bone is chosen, i.e. sagittal or coronal. MRI is superior to technetium bone scanning because tumor related hyperemic osteoporosis is not depicted on MRI and is therefore not a source of false-positive readings. MRI has an almost perfect correlation ($r=0.99$) with pathologic/morphologic examination; CT has a less substantial correlation ($r=0.93$); ^{99m}Tc methylene diphosphonate (MDP) scintigraphy has a weak correlation ($r=0.69$).^{3,8}

The osseous tumor margin may be obscured by the presence of intraosseous edema. Often a double margin can be visualized. The margin nearest to the center of the tumor represents the true tumor margin, whereas the outer margin represents the margin of the edematous reactive zone towards normal bone

marrow. Differentiation can be facilitated by using gadolinium. Tumor and the edematous reactive zones display different enhancement patterns: a well-vascularized tumor will enhance more rapidly than the reactive zone, but usually (for instance in osteosarcoma) the intraosseous reactive zone will enhance more than the tumor itself on images taken 5 min after contrast injection. Furthermore, enhancement of the edematous reactive zone is, as a rule, more homogeneous than that of tumor. The intraosseous reactive zone is usually not a clinical problem, because it disappears after one or two cycles of chemotherapy. The true tumor margin is then easily identified.

Caution is needed in the diagnosis of skip metastases. Skip metastases, as may be encountered in patients with osteosarcoma and Ewing's sarcoma, are detected with bone scintigraphy unless the size is below the detection threshold. Skip lesions of less than 5 mm may thus pose a diagnostic problem. Imaging of the entire bone on T_1 -weighted images by using a large field of view may be of help.

5.2 Cortical Involvement

Destruction of cortical bone is not a diagnostic problem since it can be evaluated on plain radiographs and, if necessary, with tomography or CT. MR images are also able to visualize the status of cortex. Invasion of cortex by tumor is best shown on T_2 -weighted images as a disruption of the cortical line and replacement of cortex by the high signal intensity of tumor. The sensitivity and specificity of MRI (92% and 99% respectively) were not found to be significantly higher than the sensitivity and specificity (91% and 98% respectively) of CT.^{3,8} MRI is superior to CT in visualizing sclerotic osteosarcomas, because the signal intensity of osteosclerotic tumor is still slightly higher than the low signal intensity of normal cortex. The high density of osteosclerotic tumor and cortex may be indistinguishable on CT.

5.3 Involvement of Muscular Compartments

MRI is significantly superior (sensitivity 97%, specificity 99%) to CT in identifying muscle compartments containing tumor.^{3,8} The superior performance of MRI is based on the display of tumor relative to muscular compartments with, compared to CT, superior contrast in the ideal imaging plane. The presence of peritumoral edema is, as a rule, easily identified because of its slightly different signal intensity compared to that of tumor, and especially because of the fading margins of edema as opposed to the distinct margin of the (pseudo)capsule of the tumor. However, accurate delineation of the tumor–edema interface can be rather difficult. Differences in signal intensity on multiple echoes and enhancement following administration of gadolinium may be used to differentiate tumor from edema.

5.4 Vascular Involvement

Vessels are more often displaced than encased by tumor. The relationship between tumor and neurovascular bundle is easily evaluated on T_2 -weighted images because normal flow in

a vessel results in low or absent signal intensity, the so-called 'flow void phenomenon.' The lumen of the vessel may have a higher signal intensity due to paradoxical enhancement, even-echo rephasing, or slow flow caused by compression. CT (sensitivity 36%, specificity 94%) and MRI (sensitivity 92%, specificity 98%) provide more information than angiography (sensitivity 75%, specificity 71%) because large vessels are, especially with MRI, well visualized in relation to the tumor.^{3,8}

5.5 Joint Involvement

CT (sensitivity 94%, specificity 90%) and MRI (sensitivity 95%, specificity 98%) are both able to demonstrate joint involvement with high accuracy.^{3,8} Joint involvement is sometimes more accurately demonstrated on MR images than on CT, because the articular surfaces may be parallel to the transverse CT plane. Cartilage is an effective barrier that is not easily crossed by tumor. Osteosarcoma and giant cell tumor are the tumors that are able to cross cartilage. When assessing possible joint involvement, the number of false-positive readings is much higher than the number of false-negative readings. When in doubt, the joint usually is not affected. Joint effusion with or without hemorrhage, often but not always a secondary sign of a contaminated joint, is easily identified on CT and MRI.

6 RECURRENCE

Detection of recurrent or residual tumor following initial treatment is a challenging problem for diagnostic imaging. A large recurrent tumor mass may be detected at clinical examination, with radiographs or by CT. Small recurrent tumors are difficult to define in relation to posttherapy changes caused by surgery, radiation therapy, and chemotherapy. The matter is further complicated when fixation devices have been used in reconstructive surgical procedures. These devices cause susceptibility artifacts on MRI. Even when no hardware is used, susceptibility artifacts, caused by metallic particles left behind after instrumentation, can degrade the MR images.

Despite these drawbacks, MRI can be used to detect recurrence (Figure 4). A recurrence is very likely (sensitivity 96–100%) when, following surgery, with or without chemotherapy, a mass is seen on MRI which is characterized by a high signal intensity of Gd-DTPA enhanced or T_2 -weighted images.⁹ Cystic masses without tumor have a high signal intensity on T_2 -weighted images, but do not enhance after intravenous administration of Gd-DTPA. A tumor recurrence is very unlikely when, following surgery, no enhancement or a low signal intensity on T_2 -weighted images is found. However, knowledge of the signal intensity of the primary tumor prior to therapy is crucial, especially when the primary tumor was characterized by a low signal intensity on T_2 -weighted images.

When an equivocal lesion is detected, follow-up studies, biopsy or other imaging studies such as radiographs or ultrasound may be helpful. Radiation therapy adds to the confusion because it may induce inflammatory, reactive changes that may be indistinguishable from tumor recurrence. These reactive

Figure 4 MRI images obtained with a 1.5 T imager of a patient with enchondromatosis and recurrent chondrosarcoma after resection and reconstructive surgery. (a) Coronal large field of view, T_1 -weighted (600/20) spin echo images show cartilaginous tumors in both proximal tibias. Marked susceptibility artifacts, secondary to metallic hardware left by the orthopedic surgeon, are seen in the left femur and proximal right tibia. (b) Axial T_2 -weighted (2000/100) spin echo images show a lobulated soft tissue recurrence posterior to the artifacts within the femur. (c) The soft tissue mass has an atypical low signal intensity on this T_1 -weighted (600/20) image. (d) After injection of Gd-DTPA the serpiginous enhancement pattern indicative of recurrent well-differentiated chondrosarcoma is easily appreciated, despite the marked susceptibility artifacts

changes are characterized by a high signal intensity on static Gd-DTPA enhanced and T_2 -weighted images, and may persist for more than a year. However, reactive lesions usually confine themselves to the space available and, unlike tumor recurrence, do not present themselves as space occupying expansile masses. Dynamic MRI can be used to differentiate reactive tissue from viable tumor. Viable tumor typically enhances 6 s after arrival of gadolinium complex in the artery. When detection of early recurrence is of vital importance, or when there is a high risk of recurrence, a baseline study obtained 3–6 months after surgery may be of help.

7 MONITORING CHEMOTHERAPY

Preoperative (neoadjuvant) chemotherapy of bone sarcomas has increased the feasibility of limb salvage procedures. As a consequence of chemotherapy, a soft tissue tumor mass may shrink and, in combination with encapsulation of the residual extramedullary tumor mass, improve surgical conditions (down staging). However, identification of good and poor respondents is a challenging and controversial exercise.¹⁰ Assessment of viable and necrotic tumor at histology is the gold standard.

Spontaneous necrosis of up to 50% is not uncommon in high-grade malignancies. Therefore a histologic good response is defined as the presence of 10% or less viable tumor tissue. A change of tumor volume and signal intensity in osteosarcomas and Ewing sarcoma may correlate with response to chemotherapy. Despite major limitations, several qualitative and quantitative MR parameters contribute to the differentiation of good and poor respondents during and after preoperative chemotherapy.

Increase in tumor volume without hemorrhage and increase of signal intensity on T_2 -weighted images in patients with osteosarcoma, even after the first cycle of chemotherapy, indicates poor response.¹¹ At present there are no reliable criteria for identifying good respondents on native MRI.

Reduction of tumor volume in Ewing sarcoma is characteristically seen in all patients with Ewing sarcoma after successful, or unsuccessful, chemotherapy.¹⁰ A 75% decrease in tumor volume, or complete absence of a residual soft tissue mass after chemotherapy, are consistent with good response. Resolution of the soft tissue mass in Ewing sarcoma is frequently accompanied by reactive subperiosteal bone formation, which may result in the development of an inhomogeneous cuff of tissue encircling the original cortex.

Progressive ossification of the periosteal mass may reflect healing of these tumors, but the presence of minimal residual disease in this peripheral area cannot be excluded with any imaging modality.

A well-defined rim of low signal intensity forming a margin for the extramedullary tumor compartment represents a fibrous pseudocapsule continuous with the periosteum; however, there is no correlation with the percentage of tumor necrosis.^{10,11} Although this qualitative sign cannot be used as a differentiating criterion between good and poor respondents, the improved tumor demarcation can facilitate the surgical resection.^{10,11}

Following chemotherapy, the amount of viable residual tumor can be assessed by dynamic gadolinium-enhanced images. Viable tumor enhances within 6 s after arterial enhancement. Non-viable tumor components enhance later or not at all.¹²

8 BONE METASTASES

Bone metastases primarily occur in the red bone marrow of the axial skeleton. We therefore focus here on the vertebral column. Conventional radiographs have a very low yield in depicting skeletal metastases when these are still located in the bone marrow. The origin of metastatic deposits is within the bone marrow of the vertebral body. Metastatic tumor may fill the marrow and leave cortical bone intact. Detection of metastatic disease can occur at a much earlier stage when destruction of cortical bone is present. The contours of collapsed vertebral bodies can suggest the nature of the underlying disease, but conventional radiography alone is unreliable in differentiating between benign and malignant causes of vertebral body collapse.

MRI can be performed using several pulse sequences; spin echo, TSE, STIR, GE, and out-of-phase chemical shift imaging. Each pulse sequence has its own imaging features and will exhibit normal bone marrow and pathology in a characteristic manner. The signal intensities reflect the histology of the tissue. Typically, metastases display a low signal intensity on T_1 -weighted sequences and a high signal intensity on T_2 -weighted sequences. There are exceptions, such as in sclerotic metastases which exhibit a low signal intensity on all pulse sequences, and lipoblastic metastases which have a relatively high signal intensity on T_1 -weighted images.

In the STIR pulse sequence, yellow marrow signal is nulled, such that bone marrow appears black. T_1 and T_2 values other than those for fat are additive. Lytic metastases, because of their high water content, produce an increase in both T_1 and T_2 relaxation times. This will enhance the contrast between lytic metastases and bone marrow. Often lytic metastases are better depicted on STIR images than on T_1 -weighted spin echo images. Early edema (10–14 days) after radiation therapy can typically be seen earlier on STIR images than on T_1 - or T_2 -weighted spin echo images.

Contrast between normal bone marrow and tumor can also be increased by using the difference in resonance frequency between aliphatic and water protons. Out-of-phase images will increase image contrast in the case of lytic bone marrow metastases. Fat suppression with presaturation pulses may further

increase contrast on T_2 -weighted sequences. Fat presaturation may be used in combination with opposed-phase imaging.

Gadolinium will further increase sensitivity when used in combination with fat suppression. It may also increase the specificity of MRI, as metastatic deposits in vertebral bodies will exhibit diffuse enhancement of signal intensity on T_1 -weighted images, whereas osteoporotic collapsed vertebral bodies will show band-like enhancement. Some authors, however, have found that the use of Gd-DTPA can be disappointing in the differential diagnosis of malignant and benign tissues.

T_1 - and T_2 -weighted (STIR or fat suppression) images will constitute a sufficient routine imaging protocol. Additional imaging in orthogonal planes will render valuable information in the case of soft tissue involvement. Gadolinium should be reserved for selected cases such as differential diagnosis between malignant and benign collapsed vertebrae and where there is suspected leptomeningeal tumor spread.

MRI is more sensitive in the detection of vertebral metastases than is bone scintigraphy.¹³ This is not surprising since MRI visualizes bone marrow directly rather than depending on secondary signs such as new bone formation.

Although the MR characteristics of metastatic disease do not always allow reliable differentiation between benign and malignant disease, MRI is still more specific than bone scintigraphy in distinguishing between benign and malignant disease. For instance, by means of MR examination it is usually possible to make a reliable distinction between degenerative bone disease in the vertebral column and malignant infiltration. Morphologic characteristics of the lesion and adjacent disk must be taken into account. Loss of height of the intervertebral disk can be seen in degenerative disease and in diskitis, whereas the shape and height of the disk is usually preserved in metastatic diseases. In diffuse bone marrow lesions, the intervertebral disk may show a high signal intensity relative to the decreased signal intensity of abnormal bone marrow on T_1 -weighted SE images.

The morphology of vertebral bodies and the signal intensity changes of bone marrow, particularly in relation to the vertebral endplates, may assist in differentiating between benign and malignant compression fractures. In old osteoporotic compression fractures the signal intensity is typically normal (fat), whereas in malignant compression fractures an abnormal signal intensity due to replacement of bone marrow is seen. In the (sub)acute phase, an inhomogeneous increase in signal intensity on STIR or T_2 -weighted images, or a sharply delineated isointense vertical band of preserved normal (fatty) bone marrow along the dorsal aspect of the compressed body, indicates a benign fracture. The abnormal signal intensity in benign fractures may have the shape of a horizontal band. Fractures at multiple levels with preservation of normal bone marrow, vertebral body fragmentation, and disk rupture also indicate benign disease. Signs in favor of malignancy are: homogeneous signal intensity changes; convex anterior, and especially posterior, contour; cortical destruction; multiple levels with abnormal signal intensity, but without fracture; and abnormal signal intensity in posterior elements. Paraspinal masses are more conspicuous in malignant disease, but can be seen in both traumatic and malignant cases. Care must be taken in interpreting MR examinations in recently collapsed vertebral

bodies as they can show signal intensities indistinguishable from metastatic disease.

Currently, bone scintigraphy remains the screening procedure of choice because it is readily available, and it allows imaging of the entire skeleton in a time effective way. However, secondary to increased sensitivity, specificity, and faster pulse sequences, the role of MRI is increasing. MRI can visualize metastatic disease when bone scintigraphy is falsely negative. Thus MRI is currently indicated when a strong clinical suspicion is combined with a negative bone scan.

MRI may also elucidate the true nature of hot spots in the vertebral column in cancer patients, as it can often assist in making a distinction between malignant and benign disease. MRI can also be helpful in the guidance of biopsies.

In order to rule out compressive myelopathy or to establish soft tissue extension of tumor tissue, multiplanar MRI offers unique imaging features. The use of MRI is helpful in determining the local extent of metastatic disease when planning palliative surgery or radiation therapy.

1 INTRODUCTION

MRI is an important tool in the radiological evaluation of peripheral joint disease. Previously available noninvasive imaging techniques include X-ray and ultrasound imaging. X-ray techniques (plain radiographs and computerized tomography) are able to image cortical bone but are not sensitive in imaging medullary bone disease or intra-articular soft tissues.^{1,2} Ultrasound can evaluate soft tissue structures but is limited in its ability to visualize internal structures in joints and detect some soft tissue diseases.³ Nuclear medicine bone scintigraphy has also been used to detect articular pathology, but is not commonly used because of its lack of specificity and poor spatial resolution.^{4,5} MRI is capable of demonstrating the anatomy of the various components of peripheral joints in exquisite detail, including muscles, tendons, ligaments, nerves, blood vessels, fat, and osseous structures.^{6,7} In addition to its high spatial resolution, MRI displays excellent contrast between musculoskeletal soft tissues because differences in chemical structures lead to different T_1 and T_2 values. These differences in relaxation times can be exploited to generate images with striking contrast between normal tissues and between normal and pathologic tissues. Intra-articular injection of contrast material (arthrography) allows X-ray techniques to visualize the surfaces of intra-articular structures, but X-ray arthrography is both invasive and insensitive to numerous pathologic conditions that do not manifest with surface irregularities.⁸ MR arthrography is now widely used for the evaluation of specific articular pathology because it combines the sensitivity of arthrography for surface abnormalities with high soft-tissue contrast.⁹⁻¹¹ For these reasons, many consider MRI to be the modality of choice for noninvasive imaging of peripheral joint disease.

2 BASIC TECHNIQUES

Most MRI of peripheral joints is performed with two-dimensional spin echo pulse sequences.⁶ This is a basic (90°–180°) sequence, with the time between successive 90° pulses denoted TR and that between 90° pulse and the signal acquisition denoted TE . A slice selection gradient is applied during each rf pulse to limit the excitation to the desired anatomic plane of interest. Perpendicular gradients are also used to provide frequency and phase encoding. The basic pulse sequence

is repeated 128, 192, or 256 times, each time with a different phase-encoding gradient. The signals or echoes from each acquisition are collected and processed using a two-dimensional Fourier transform to generate the final medical image. Many varieties of the basic scheme are now in clinical use.¹²

By adjusting the TR and TE , the signal can be manipulated to have lesser or greater degrees of T_1 or T_2 contrast. Hence, an image acquired with a sequence with a short TR (~600 ms) and short TE (~15 ms) is referred to as a T_1 -weighted image. Similarly, if the TR is long (~2000–4000 ms) and the TE is long (~80 ms), this is referred to as a T_2 -weighted image. If the TR is long but the TE is short, then many refer to this as a proton density-weighted image.

Most structures in peripheral joints have fairly characteristic T_1 and T_2 values that make them easy to distinguish on the spin echo images. For instance, fat has a short T_1 , so it has bright signal intensity on T_1 -weighted images. Ligaments, tendons, and bone cortex have a paucity of mobile protons and therefore demonstrate low signal intensity on all pulse sequences. Muscle tissue also has a fairly long T_1 and therefore looks dark on a T_1 -weighted image, although not as dark as tendon or ligament. Bone marrow can have intermediate to bright intensity on T_1 -weighted images depending on the fat content (nonhematopoietic or 'yellow' marrow has more fat than hematopoietic or 'red' marrow). Fluid within joints has a long T_1 and a long T_2 ; hence it will appear dark on T_1 -weighted images and bright on T_2 -weighted images.

Most pathologic tissues have increased edema compared with their normal counterparts. This increased water content causes prolongation of their T_1 and T_2 values. Hence, on T_1 -weighted images, abnormal tissues tend to look dark, whereas on T_2 -weighted images, these tissues generally look abnormally bright. Most lesions are fairly obvious on T_2 -weighted images. However, the presence of bright signal on a T_2 -weighted image is a nonspecific finding: many disease processes (i.e., tumor, infection, trauma, etc.) can cause this appearance and other clues (such as lesion morphology and location) must be sought in order to make a more specific diagnosis.

In particular, abnormalities within ligamentous, tendinous, and other fibrocartilaginous structures (such as the menisci in the knee and the labra in the shoulder) manifest themselves as foci of abnormally increased signal within a usually homogeneously dark structure.^{4,13} Normally, there are few mobile water molecules within these structures capable of generating any significant signal. The water that does exist within them is bound to the large macromolecules such as cartilage and is incapable of free translation and rotation.¹⁴ The protons within these bound water molecules have very short T_2 values and therefore do not generate any detectable signal. However, if the collagen matrix undergoes degeneration with microscopic tears, then small amounts of water can be trapped in the interstices. These water molecules are more mobile and therefore have slightly longer T_2 values, which can be detected on short TE images (i.e., T_1 -weighted and proton density-weighted images). The T_2 values are still too short to generate signal on longer TE images (i.e. true T_2 -weighted images). There may also be a secondary T_1 shortening effect that might contribute signal on T_1 -weighted images. With degenerative disruption of macromolecules, water protons may be exposed to protons deep in the macromolecules. This close proximity between the two sets of protons allows for some magnetization exchange to occur,

Figure 1 A sagittal proton density-weighted image of a knee (TR 2000, TE 25) demonstrating tear within the lateral meniscus. These are visualized as increased signal (white arrowhead) within the normal low signal of the menisci. A larger area of bulk fluid is seen anteriorly (white arrow) representing an intrameniscal cyst

with resulting shortening of the T_1 time.¹⁴ The hallmark of this type of pathologic process is increased signal on the proton density-weighted images but *not* on the T_2 -weighted images.¹³

In the presence of more significant trauma, macroscopic amounts of free fluid can be present. Clinical examples would include complete rotator cuff tears and large meniscal tears with development of intrameniscal cysts.^{4,13} In these settings, the abnormal area would show increased signal on *both* the proton density- and T_2 -weighted images (see Figures 1 and 2).

Figure 2 A sagittal T_2 -weighted image (TR 2000, TE 80) of the same knee as in Figure 1 clearly showing the bulk fluid (white arrow) of the intrameniscal cyst. The T_2 of the bulk fluid is prolonged, making this fluid visible. However, the meniscal tears (white arrowhead) are considerably less apparent because their T_2 values are not as prolonged

Another commonly used pulse sequence is the STIR or short τ inversion recovery sequence. This pulse sequence consists of $(180^\circ - \tau - 90^\circ - 180^\circ)$, where τ is the delay time between the initial 180° inversion pulse and the 90° pulse. In a STIR sequence, τ is set to the null point of fat, i.e. the length of time it takes for the fat to recover to a point of zero longitudinal magnetization after an initial inversion. At a typical field strength of 1.5 T, the appropriate value of τ is approximately 160 ms.

In a STIR sequence, the signal intensity of the tissue is directly related to its T_1 and T_2 values. Tissues with short T_1 and T_2 values such as fat show little or no signal, whereas tissues with long T_1 and T_2 values have bright signal. Because most pathologic tissues have prolonged T_1 and T_2 relaxation times they are bright on STIR images even more so than on T_2 -weighted images. This is especially valuable when imaging at mid and low magnetic fields (0.2–0.5 T). However, as with a T_2 -weighted image, bright signal is not specific for any one disease process and other information (such as morphology and location of the lesion) must be considered to make a more specific diagnosis.

Another set of pulse sequences commonly used in musculoskeletal MRI is the RARE sequence,¹⁵ which is also known as *fast spin echo* (FSE) or *turbo spin echo*.¹⁶ In this pulse sequence, an initial 90° pulse is followed by a rapid succession of 180° pulses to generate a series of echoes known as an echo train. Typically 4, 8, or 16 echoes are generated per excitation, each preceded by a different phase-encoding gradient. Hence, several lines of k -space are acquired per excitation, resulting in a considerable saving in scanner time. However, the TE values are not uniform within the image: some of the echoes making up the image will have shorter TE s, whereas others will have longer TE s. This can result in a variety of image artifacts including blurring and loss of resolution and changes in image contrast.¹⁷ Also, because some pathological processes (such as meniscal tears in knees) demonstrate increased signal on short TE sequences but not on long TE sequences, it is possible that the mix of long and short TE s in a FSE image might make it less sensitive to subtle lesions than a standard spin echo image.¹⁸ For this reason, at our institution the following compromise is used: for the key anatomic plane of a joint (which is the sagittal plane for knees and the oblique coronal plane for shoulders), a slower standard spin echo pulse sequence is used to generate proton density and T_2 -weighted images. For the other anatomic planes, FSE is used. In this way, a reasonable balance between scanning time and diagnostic accuracy is maintained. However, as interpreters get more experience with the vagaries of these sequences on individual scanners, more sequences are being converted to the faster techniques. Spectral fat saturation is often advocated with the use of FSE imaging in the musculoskeletal system to eliminate increased signal from fat on FSE T_2 -weighted images.¹⁹

Gradient echo pulse sequences are only infrequently used in MRI of peripheral joints. They are fairly sensitive for the same pathological processes that are detected by short TE spin echo sequences. However, the soft tissue contrast is worse with gradient echo sequences than with spin echo sequences. This is because the contrast in gradient echo sequences is dependent on differences in T_2^* rather than in T_2 .²⁰ In clinical MR imaging, most of the T_2^* effect is caused by field inhomogeneities and other factors not dependent on the biomedical make-up of

the tissue. Hence, the signal from the tissues undergoes T_2 decay before the differences in the true tissue T_2 s can manifest themselves. For this reason, most soft tissues have very similar appearances and signal intensities on gradient echo images, regardless of the tissue type or the degree of involvement by pathology. Nevertheless, some investigators use gradient echo sequences because the short TR s allow 3-dimensional Fourier transform acquisitions in a reasonable time period for isotropic high-resolution imaging. This may be valuable in imaging the labrum and articular cartilage.^{13,21}

In certain settings, intravenous or intraarticular gadolinium may prove useful for diagnosis. Gadolinium is a paramagnetic metal which can be bound to an organic chelating agent such as diethylenetriaminepentaacetic acid (DTPA). In the doses used in clinical practice, the main effect of intravenous gadolinium is to shorten the T_1 relaxation times of the perfused tissues. This causes them to appear brighter on T_1 -weighted images. Some investigators have found this useful in evaluating possible recurrences of soft-tissue neoplasms following surgical resection.^{22,23} Intravenous gadolinium can also be useful in determining if a soft-tissue mass with long T_1 and long T_2 is cystic or solid. A cystic lesion would not show any signal enhancement following contrast administration whereas a solid lesion would. Similarly, in the setting of a soft-tissue infection, it can be very difficult to tell the difference between an area of phlegmonous and inflamed solid tissue and a drainable fluid collection. On a postgadolinium image, the phlegmon should enhance, whereas the fluid collection should not enhance.^{24,25}

Gadolinium can also be injected into a joint space in the form of a dilute mixture of saline and gadolinium-DTPA.^{9,10} This forms a positive contrast on T_1 -weighted images that distends the joint capsule and helps delineate adjacent structures. This type of MR arthrography has proven particularly useful in the shoulder, where subtle abnormalities in the cartilaginous labra can be better appreciated following contrast injection.²⁶ However, this converts the MR study from a noninvasive procedure to an invasive procedure, with resultant discomfort and potential risk to the patient. (Some radiologists also inject saline without gadolinium, which produces a similar arthrographic effect on T_2 -weighted images).²⁶ MR knee arthrography is helpful in some patients who have had previous meniscal repair.²⁷

3 DISEASE ENTITIES

3.1 Trauma

MR has proven to be a valuable tool in the evaluation of acute trauma to peripheral joints as well as in evaluation of chronic trauma and degeneration. For instance, within the knee joint (the most commonly imaged peripheral joint), MR can be used to detect partial and complete tears of key anatomic structures including the medial and lateral collateral ligaments, the anterior and posterior cruciate ligaments, and the medial and lateral menisci.⁶ Injuries to these structures can be detected by identifying abnormally increased signal within these normally low-signal structures. Other important radiographic signs include alterations in the contour and morphology of these structures, and the presence of edema in the surrounding soft tissues (manifested as high signal intensity on T_2 -weighted

Figure 3 A sagittal proton density-weighted image (TR 2200, TE 20) of the ankle showing a tear of the achilles tendon. The tear is the area of increased signal (arrow) within the normally dark substance of the tendon (arrowheads). Notice the focal thickening of the tendon at the site of the tear

images). These principles apply to evaluation of ligamentous and tendinous, and muscular structures at all joints, including the rotator cuff of the shoulder and the achilles tendon in the ankle (see Figures 1–3).^{13,28,29}

MRI has also proven to be sensitive in the detection of radiographically occult fractures.^{28,30} Often these fractures produce a characteristic linear pattern of bone marrow edema, which can be visualized as a region of low signal intensity within the marrow on T_1 -weighted images and high signal intensity within the marrow on T_2 -weighted images. Detection of these fractures can have important therapeutic implications, so MRI should be strongly considered in the setting of a patient with clinical findings suspicious for fracture with normal radiographs. Many investigators feel that MR is at least as sensitive for detection of such fractures as the other major technique, bone scintigraphy, and is more specific (see Figure 4).^{31,32}

Traumatic lesions of the articular cartilage and subchondral bone can also be detected with MRI. In an acute setting, these are known as osteochondral fractures, whereas in the setting of chronic repetitive microtrauma, these lesions are referred to as osteochondritis dissecans. Pertinent MR findings which may be seen include disruption or thinning of the articular cartilage, alterations of the contour of low-signal subchondral bony plate (which may be accompanied by abnormal high signal within the normal low signal of cortical bone), and edema in the adjacent bone marrow.³³

3.2 Infection

Another common use of MRI is in the evaluation of suspected infections of peripheral joints.^{24,34} MR can detect the presence of abnormal fluid within a joint space, but cannot determine if the fluid is sterile or infected (i.e., if the patient has a bland joint effusion or a septic arthritis). MR is also useful in the evaluation of osteomyelitis. The principal finding in

Figure 4 A coronal T_1 -weighted image (TR 600, TE 15) of the hips showing a fracture of the right femoral neck (straight arrow). The abnormal low signal in the marrow is caused by edema. For comparison, the marrow signal in the left femoral neck is normal (curved arrow)

osteomyelitis is bone marrow edema (manifested by the usual low signal intensity in the marrow on the T_1 -weighted images and high signal intensity on the T_2 -weighted image). Osteomyelitis is also often accompanied by inflammatory changes in the adjacent soft tissues. If an area of soft tissue edema is identified, then MR with intravenous gadolinium administration can help to determine if there is a component of drainable fluid within the inflamed phlegmonous region.^{24,25} This is extremely valuable in the evaluation of the diabetic foot.³⁴ As discussed above, a fluid collection should not enhance, whereas the phlegmonous component should (see Figure 5).

3.3 Arthritis

The role of MRI in evaluation of arthritis patients is fairly limited. MR can detect the findings seen in osteoarthritis,

Figure 5 A coronal T_1 -weighted image (TR 800, TE 20) of the hips showing marrow edema caused by osteomyelitis in the left femoral neck (white arrow). The signal intensity is similar to that of the edema caused by the fracture in Figure 4, but the abnormal area is more extensive and ill-defined. This is more compatible with an infectious process. Edema is a nonspecific finding; clinical history and morphologic clues are often necessary to distinguish between various disease entities

Figure 6 A coronal T_1 -weighted image (TR 500, TE 21) of the wrist showing avascular necrosis of the proximal pole of the scaphoid bone (straight arrow), with abnormally low signal intensity within the marrow. The distal pole of the scaphoid bone has relatively normal signal intensity within the marrow (curved arrow)

including the cartilage loss, subchondral sclerosis and cyst formation, and osteophytes.³⁵ In rheumatoid arthritis, MR may be helpful in delineating the exact extent of the inflamed pannus tissue. On standard MR images, the pannus can look similar to joint fluid, but after the administration of intravenous gadolinium, the pannus should enhance intensely. MR is also sensitive for early detection of erosions, which may also be helpful in patients with rheumatoid arthritis or other erosive arthritides.³⁶

3.4 Ischemic Disease

MR is sensitive in the evaluation of ischemic bone disease including avascular necrosis and bone infarcts.^{37,38} The devascularized portion of bone becomes edematous initially. Later, as fibrovascular tissue replaces granulation tissue the T_2 relaxation time shortens (Figure 6).

Some investigators have found that dynamic gadolinium enhancement studies are useful in assessing the prognosis of involved bone.^{39,40} For instance, with avascular necrosis of the femoral head and scaphoid fractures, patients with lesions which enhanced following intravenous gadolinium administration may have an improved prognosis over patients whose lesions did not enhance. Further work remains to be done to see if this is true in other areas of the body.

3.5 Neoplasms

MR has proven valuable in staging of osseous and soft tissue neoplasms.^{22,41–45} With MRI, one can evaluate the anatomic extent of the tumor and the integrity of adjacent neurovascular bundles. MR is helpful in determining whether a tumor of soft tissue origin involves adjacent bone and if a tumor of bony origin involves adjacent soft tissue structures. The extent of the bone marrow involvement can also be evaluated with MRI. Most neoplasms have prolonged T_1 and T_2

values, resulting in the typical dark appearance on T_1 -weighted images and bright on T_2 -weighted images. The contrast between the tumor and bone marrow or subcutaneous fat is most marked on T_1 -weighted or STIR images because fat has such a short T_1 in contrast with the long T_1 of the tumor. On the other hand, T_2 -weighted images are better at demonstrating the difference between the tumor and normal muscle or normal neurovascular structures.

These tumors are often surrounded by a halo of edema, which also has similar signal characteristics to the main tumor. In this case, the area of signal abnormality on the images is larger than the size of the actual tumor. In this setting, evaluation with intravenous contrast and fat-saturated T_1 -weighted images may be valuable.^{46,47}

MRI is not very specific for most tumor cell types. The only major exceptions are lipomas, which are nearly entirely composed of fat.⁴⁸ These can be identified by the characteristic signal intensity equal to normal fat on all pulse sequences, as well as by secondary signs such as chemical shift artifact. If a fat suppression pulse sequence is used (where rf energy is applied to the fat peak prior to image acquisition), or a STIR series is acquired, the signal from lipomas should disappear. If a tumor demonstrates all of these signal characteristics, and does not contain any significant amounts of nonfatty tissue, then the diagnosis of benign lipoma can be confidently made.

Most soft tissue tumors have a nonspecific appearance, and the main role of MR is to evaluate for anatomic extent. This is useful in planning biopsies, surgical resections, and/or radiation therapy. MRI is also helpful in the evaluation of suspected recurrence following resection. In this setting, some investigators have found that intravenous gadolinium is helpful in distinguishing recurrent tumor from normal postoperative reaction.^{29,49,50} Examples of bone and soft tissue tumors are shown in Figures 7–10.

4 FUTURE DIRECTIONS

There are several technical advances that may have promising applications in musculoskeletal MRI. One of these is MR microscopy. With current clinical MRI, the spatial resolution is on the order of 0.5–1.0 mm per pixel. With specialized gradients and other MR microscopy techniques, this can be improved by a factor of approximately 10. If this is done, then it becomes possible to evaluate structures such as articular cartilage in much greater detail. Instead of appearing as a thin stripe of signal, 2 or 3 pixels thick, the articular cartilage will be a broad band, 20 or 30 pixels thick. (See Figure 11). It may then be possible to evaluate subtle pathology within the various sublayers of articular cartilage.^{51–53} Any technique that can determine the presence or absence of early changes in rheumatological disease is also helpful, particularly for evaluating the efficacy of various treatments.

Other potentially important advances are the various diffusion and perfusion imaging techniques. The musculoskeletal system is well suited for application of these techniques because these body parts can be kept fairly immobile during scanning, which is a requirement for successful use of these techniques. Although this has not yet been proven, it is possible that some pathological processes may manifest themselves

Figure 7 A coronal T_1 -weighted image (TR 800, TE 20) showing a large destructive mass in the lateral femoral condyle (arrow), caused by metastatic renal cell carcinoma

as alterations in either local perfusion or alterations in the local diffusion coefficients before one sees evidence of gross edema and prolongation of T_1 and T_2 relaxation times.⁵⁴

Magnetization transfer contrast is another technique that may prove useful in musculoskeletal application, particularly in

Figure 8 A transaxial T_2 -weighted image (TR 2117, TE 80) of the same lesion shown in Figure 7, showing increased signal intensity within the mass (arrow) caused by T_2 prolongation

Figure 9 A coronal T_1 -weighted image (TR 600, TE 20) of the right thigh showing a round mass in the medial soft tissues (white arrow). The mass (a malignant fibrous histiocytoma) is difficult to identify because it has similar signal intensity to normal muscle on this sequence

Figure 10 A coronal STIR image (TR 2200, TE 35, τ 160) showing the same lesion as that shown in Figure 9 (arrow). The mass is much more conspicuous on the STIR image

Figure 11 A T_1 -weighted MR microscopy image showing the articular cartilage as a thick band of intermediate signal intensity (arrows)

articular cartilage. Some investigators have demonstrated a large magnetization transfer effect due to the high degree of interaction between water and collagen macromolecules in articular cartilage. Specifically, it has been shown that the majority of the magnetization transfer effect is caused by interactions between water and the collagen matrix, and not between water and the proteoglycan component of cartilage.⁵⁵ This finding may prove useful in evaluation of subtle cartilaginous pathology, perhaps in conjunction with MR microscopy.

MR spectroscopy has existed for many years. Some work has been done using spectroscopy to evaluate metabolic diseases of muscles, but none of these techniques is in routine clinical use as yet. In recent years several manufacturers have developed smaller, relatively inexpensive scanners designed to scan extremity joints. These scanners are often 50 to 80% less expensive than traditional whole-body scanners and can be installed in standard clinic examining rooms (e.g. Esaote, Genoa, Italy). Though these scanners typically operate at low magnetic fields (0.2 T) and produce relatively noisy images, the price, convenience, and comfort is highly attractive to many patients. These devices are currently the fastest growing segment of the MR market.

5 CONCLUSIONS

In summary, MRI is a powerful tool in noninvasive evaluation of abnormalities of peripheral joints. The combination of high spatial resolution and sensitivity to local alterations in water content and T_1 and T_2 relaxation times makes it ideal for demonstrating pathological processes. MR has a role in the evaluation of many disease processes including trauma, infection, vascular compromise, and neoplasm. Additional techniques that may prove clinically useful in the future include MR microscopy, diffusion and perfusion imaging, magnetization transfer contrast, MR spectroscopy, and speciality scanners.

Peripheral Muscle Metabolism Studied by MRS

Peter A. Martin, Henry Gibson, and Richard H. T. Edwards

Magnetic Resonance Research Centre and Muscle Research Centre,
The University of Liverpool, Liverpool, UK

1 INTRODUCTION

Muscle is a unique biological machine providing the main method of generating motive force, work, and power: it constitutes some 40% of total body cell mass in normal man. It is easily accessible for study and capable of great versatility in performance from a delicate touch to a powerful punch or from running a sprint to a marathon. Muscle metabolic rates can rapidly increase by over 100-fold. The body has nearly 600 muscles divided into three groups, skeletal (striated), visceral (non-striated), and cardiac; cardiac muscle is dealt with elsewhere (see *NMR Spectroscopy of the Human Heart*). Here we are only concerned with the muscles of the limbs, i.e., 'peripheral' skeletal muscle, which was one of the first tissues to be studied by magnetic resonance spectroscopy (MRS). Diseases of muscle (myopathies) are rare and often chronic and disabling, largely due to wasting of muscle tissue, which may be progressively replaced by fat or fibrous tissue, such as in the inherited X-linked muscular dystrophies. This creates a problem in trying to monitor muscle biochemistry because of serious partial volume effects, i.e., any volume of muscle under study contains an abnormally high proportion of fat or fibrous tissue as is readily seen on muscle biopsy. Quite different are the specific cellular enzyme and membrane defects of muscle, where this fat replacement is absent or less evident. They represent 'Nature's experiments' where the impairment is due to interference with some essential metabolic pathway. They constitute an interesting group of disorders which are particularly amenable to study by in vivo MRS. Magnetic resonance imaging (MRI) has been confined largely to the study of anatomy and gross pathology (see *Skeletal Muscle Evaluated by MRI*), whereas MRS has mostly been confined to metabolic studies of phosphorus (^{31}P)-containing compounds, although some work has been done using hydrogen (^1H)^{1,2} and carbon-13 (^{13}C).³ Fortunately, the phosphorus-containing compounds visible by MRS—phosphocreatine (PCr), adenosine triphosphate (ATP) and inorganic phosphate (Pi)—are of great interest since they are involved in the energy metabolism of the muscle cells enabling MRS to be used to study muscle energetics noninvasively.

2 MUSCLE STRUCTURE AND FUNCTION

Human muscle comprises at least two populations of fibers with different functional and metabolic characteristics. In

health, the distribution of fibers in particular muscles reflects the physiological function of the muscle, whether for postural control (e.g. soleus) or for rapid movement (e.g. biceps). Muscles are organized in bundles (fascicles) and form into groups with a particular gross structure characteristic of that muscle (e.g. pennation angle, which can be determined by MRI⁴).

Muscles work together as 'agonists' and 'antagonists' to achieve a particular force or movement. The protein chemistry and fine structural features responsible for force generation in muscle are beyond the resolution of whole body MR systems, and are, thus, not covered here.

The muscle fibers (cells) have an outer membrane, the sarcolemma, filled with a fluid, sarcoplasm, containing the endoplasmic reticulum, mitochondria, and the many peripherally located nuclei. The myofibrils, which constitute a large component of the cell, consist of a matrix of interdigitating actin and myosin protein chains. Muscle performance is achieved by the action of actin and myosin chains sliding over each other, shortening the length of the sarcomere and thus the muscle. Muscles contract in response to a nerve impulse and each muscle cell must therefore have a neuronal connection. However a single neurone will have from a few to several hundred branches, each connecting with muscle cells that all contract together. This group forms a motor unit and the recruitment of an increasing number of motor units is one of the main factors governing the control and precision of any force generated.

Initiation of a contraction depends on a nerve signal being transmitted to the muscle via a chemical messenger acetylcholine. This causes an 'action potential' to be produced in the form of a region of electrical depolarization on the sarcolemmal membrane. The action potential rapidly travels the length of the muscle cell releasing calcium from the lateral cisternae of the endoplasmic reticulum. The calcium release activates actomyosin ATPase and triggers myofibrillar cross bridge interaction and thus force generation. A single action potential produces a single twitch involving the *entire* muscle fiber. Gradation of strength depends on changing the number of muscle fibers that are active. For a prolonged contraction of greater force, multiple stimuli are used, and if the frequency of stimulation is high enough the individual twitches fuse together to produce a smoothly sustained *tetanic* contraction, which lasts longer and is several-fold stronger than a single twitch. The two basic types of skeletal muscle fibers contract at different speeds; the 'red', slow-twitch (or type I) fibers are best suited to prolonged aerobic exercise, whereas the 'white' fast-twitch (or type II) fibers are best adapted to high intensity exercise that is largely anaerobic; intermediate fiber types also occur, and their prevalence depends on the activity history of the muscle (see Table 1). The importance of the recognition of two main fiber type populations in human muscles is that regional metabolic inhomogeneity can develop within the muscle as a consequence of particular forms of muscular activity in which individual populations of muscle become fatigued to different extents, resulting in their discrete appearance in the spectra. [e.g. split inorganic phosphate (Pi) peak]. Another consideration which can confuse this interpretation is that the sensitive volume of tissue studied may include more than one agonist muscle group, of which only one may be active.

Table 1 Summary of broad characteristics of main fiber types in human skeletal muscle

Characteristic	Slow twitch, Type I	Fast twitch, Type II
Contraction time	Long	Short
Relaxation time	Long	Short
Myosin ATPase activity	Low	High
Fatigability	Low	High
Phosphocreatine content	Low	High
Oxidative enzyme activity	High	Low
Capillary density	High	Low
Mitochondria	Numerous	Few
Glycogen content	No difference	No difference
Fat content	High	Low
Myoglobin content	High	Low

3 MUSCLE AS A BIOLOGICAL MACHINE

When considering muscle function it is important to recognize the relationships between energy, force, work, and power. In the human body energy, measured in joules (J), is available for muscle metabolism via either the long- or the short-term energy supply processes. The maximum force, measured in newtons (N), that a muscle can generate (its strength), depends on the cross-sectional area of active muscle fibers. Comparison of working muscles requires that they are doing the same amount of work, i.e. force $\times$ distance, or generating the same power output (force $\times$ distance/time) which is measured in watts (W). The work done by the muscle will equal the energy expended only if the muscle is 100% efficient. Most muscular activity is about 20% efficient, the remainder of the energy being dissipated as heat. The maximum power output of the muscle depends on its maximum force *and* its velocity of shortening. During isometric exercise, when the muscle contracts without altering its length, external power output is zero; however the force-time integral can be used as an indicator of muscular activity.⁵

4 PRACTICAL ASPECTS OF ERGOMETRY

Of vital importance in the study of any particular muscle is the need to be able to measure accurately and objectively its force, work, and power output. In the body, muscles *in vivo* form part of a complex machine, with their diverse attachments to bones and the agonist/antagonist arrangement by which they work together or against each other respectively. Sensible force measurement depends on the careful design of the ergometers used. The 'man-machine interface' thus becomes of paramount importance to provide an objective work standard against which NMR measurements may be correlated. Exercise can be dynamic such as running or walking or isometric (static) as in holding various body postures or a heavy weight. Although much human activity consists of dynamic exercise the constraints of space within the magnet system mean that isometric exercise is more easily studied. Although many ergometers are available, their use in conjunction with MR systems is limited, not least because human muscle studies by MRS carried out in

the 1.5–2 T horizontal bore, whole body magnet systems, necessitate that the subject should lie down in the magnet. MR systems have magnets that are designed to have good homogeneity, but they also produce strong fringe fields. Commercially available ergometers are made of ferromagnetic materials or involve electrical motors or dynamos, which means that they will not work properly in the close proximity of strong magnetic fields of the MR system; such ergometers will in turn destroy the homogeneity of the magnetic field.

In the future, we may expect both these problems to be resolved as new magnet designs are becoming available that will enable the subject to stand up within the magnet system and carry out exercise routines such as running or cycling, which are more in keeping with normal human activity. Secondly, improved magnetic shielding is reducing the stray field of the magnet systems to such an extent that conventional ergometers can be used within 1 m or so of the MR magnet. However it is unlikely that the need for specially designed non-magnetic ergometers will disappear; indeed the opportunities opened up by this new field will require new and more sophisticated designs.

Figure 1 shows an example of an apparatus that has been used for the study of isometric exercise in the quadriceps muscle during both voluntary and electrically stimulated exercise studies.⁶ The subject lies supine with the knees bent and resting at an angle of 120° over a polystyrene foam block. The ankle is restrained by a strap which is attached to a force transducer while a wide belt across the waist prevents subjects from using their back and abdominal muscles to aid in the exercise. Stimulation electrodes strapped on with crepe bandages are applied both superior and inferior of the quadriceps to allow electrical stimulation of the muscle. The electrodes are connected via screened leads and a radiofrequency filter to a

**Figure 1** Apparatus for the study of the quadriceps muscles

commercial stimulator and consist of 2 cm² of copper over a conducting gel pad, 5 cm × 10 cm, cut from a commercial defibrillator pad. The force transducer consists of an aluminum bar and strain gauge connected to a preamplifier, the output of which passes out of the scan room via a radiofrequency filter. Visual and audio feedback of the measured force are provided to the subject from a LED bar graph and tone generator to enable the subject to make voluntary contractions to prescribed target forces. Red, yellow and green LEDs under control from the spectrometer's computer are used to tell the subject when to exercise and to provide warning of forthcoming electrical stimulation. The limb may be made ischemic (blood supply stopped) by simply inflating a thigh sphygmomanometer cuff to 100 mmHg above systolic blood pressure, thereby providing a closed system trapping metabolites and preventing oxidative recovery processes. Measurement of myographic activity is also possible without deterioration of the magnetic homogeneity.⁷

5 MRS TECHNIQUES FOR MUSCLE STUDIES

The spectacular improvement in MRI has not been matched by a comparable improvement in in vivo MRS over the 15 or so years since the introduction of the first small-bore in vivo spectroscopy systems. Clinical applications of spectroscopy have been slow to appear, and it is still not a routine diagnostic tool. An illustration of the range and quality of spectra that can be obtained is shown in Figure 2. This shows a set of spectra from the forearm of a normal boy and a dystrophic boy with Duchenne muscular dystrophy.⁸ The ¹H spectrum for the dystrophic forearm shows a decrease in the water peak and an increase in the fat peak. The ¹³C spectrum shows a lot more peaks, but at the resolution achievable with the 1.5–2.3 T of most in vivo systems, this is difficult to interpret with many overlapping peaks. The peaks due to CH₃ and CH₂ groups are clearly visible, however, and the dystrophic forearm shows a general increase in the ¹³C signal, which is most obvious in fat signals in the CH₂ region. The phosphorus spectrum shows a large peak due to PCr and three peaks due to ATP, as well as a small peak due to Pi. The dystrophic ³¹P spectrum shows a decrease in the total signal of phosphorus metabolites as the fat displaces the muscle. The utility of MRS for muscle studies depends primarily on the quality of the spectra that can be obtained. Quantitative analysis requires as good a signal-to-noise ratio (S/N) as possible for all the peaks of interest. Qualitative studies can tolerate a poorer S/N but here extra care needs to be taken in the interpretation of results. Many factors interact to influence the spectral quality, e.g. the field strength and homogeneity of the magnet, the size and location of the muscle to be studied, the magnetic sensitivity of the nucleus, e.g. ³¹P, ¹³C, ¹H, the type of radiofrequency coil to be used, the MR localization technique, and the type of muscular activity to be studied.

The first localization technique used in muscle studies was 'surface coil localization'.⁹ This is suitable for all nuclei and relies entirely on the localized but inherently nonuniform response of a simple loop antenna (the surface coil) to restrict the region from which signals would be obtained (see *Surface Coil NMR: Detection with Inhomogeneous Radiofrequency Field Antennas*); when both transmitter and receiver surface

Figure 2 Resting ¹³C, ¹H, and ³¹P NMR spectra of the forearm. The spectra on the right are from a 9-year-old with Duchenne's dystrophy, and on the left are from an age-matched control with similar skin thickness

coils are used they have a sensitive volume which forms a hemisphere penetrating to a depth of roughly one coil radius. This was later supplemented by the use of magnetic field localization techniques of which the most widely used for muscle studies has been the topical magnetic resonance (TMR) method.¹⁰ This used a static, high order (Z4) gradient to spoil deliberately the magnet homogeneity over all but the chosen small diameter, central region of the magnet; any signals coming from this uniform central volume would be sharp peaks, whereas any signals coming from outside this volume would appear as a broad hump in the baseline, which could be removed from the final spectra via a convolution difference technique.

Topical magnetic resonance had the big advantage that good localization (superior to that of a surface coil alone) can be obtained from a single acquisition, making it suitable for studies requiring time resolution of the order of 1 or 2 s. It had the disadvantage of relying on static magnetic field gradients, which could not be switched rapidly on and off, and which only produced a uniform field at the center of the magnet, requiring the muscle of interest to be located there. This put

Table 2 ^{31}P relaxation times in human skeletal muscle

	Field (T)	α -ATP	β -ATP	γ -ATP	PCr	Pi	Ref.
$T_1(\text{s})$	1.5	3.603	4.310	4.755	5.517	4.017	¹⁶
$T_2(\text{ms})$	1.5	22.2 ^a	8.1 ^a	16.1 ^a	424.3	204.7	¹⁴

^aThese measured values are probably lower than the true in vivo values due to the effects of J coupling which were not taken into account in this study¹⁷

physical and anatomical constraints on what could be studied. Thus, the TMR method rapidly fell out of favor once magnets with switched gradients became available holding the promise of combining imaging and spectroscopy in studies and pulsed gradient localization techniques, allowing localization of any volume within the (larger) homogenous region in the center of the magnet. An alternative localization strategy that has been used by some groups is to use one-dimensional, 'Rotating Frame' chemical shift imaging;¹¹ this has not been widely adopted, however, largely because of the T_2 distortion to which it is susceptible. This shows itself primarily as a decrease in the area of the β -ATP peak which is a particular disadvantage since this peak is often used as an internal reference for quantitation.

Of the many gradient localization techniques that have been introduced over the last 10 years, few of them have found practical application in muscle studies. This is because most muscle studies have used ^{31}P spectroscopy. Carbon-13 spectroscopy has been done at natural abundance,^{12,13} but generally the most useful results are obtained with the introduction of ^{13}C labeled compounds, but with greatly increased cost. Water-suppressed ^1H spectroscopy has not yet been widely applied to muscle and for the most part unsuppressed ^1H spectra are only of limited value. Compared with protons, phosphorus nuclei tend to have short T_2 relaxation times,¹⁴ which makes them unsuitable for any localization technique that relies on long echo time, spin, or stimulated echoes, e.g. Pixel-RESolved Spectroscopy (PRESS) and the STimulated Echo Acquisition Method (STEAM). One simple localization technique which has found some application in muscle spec-

troscopy is Depth-Resolved Surface coil Spectroscopy (DRESS). This consists of a conventional slice selection followed by collection of an FID signal, though the loss of some signal, particularly from β -ATP, is a disadvantage, and baseline distortions caused by the long delays between excitation and data acquisition make subsequent processing and any attempts at accurate quantitation difficult.¹⁵ The best true volume localization technique for ^{31}P spectroscopy is the Image-Selected In vivo Spectroscopy technique (ISIS). This has the advantage that it does not use spin echoes and thus is capable of giving good, undistorted spectra suitable for quantitation, but ISIS suffers from the serious disadvantage that it is a differencing technique requiring a minimum of eight signals for full volume localization. This makes it highly susceptible to motion artifacts and thus completely unsuitable for exercise studies. The quality of localization is affected by T_1 effects and thus, for muscle studies, it should ideally be run at repetition times (TR) of 15 s, making it unsuitable for short-duration time course studies.

Because of the problems associated with volume localization techniques most muscle studies still use surface coil localization alone. This presents some difficulties for quantitation since the nonuniform response of the coil results in a variation of the flip angle throughout the sensitive volume causing variation in signal strength due to T_1 and T_2 effects (see Table 2). This has been ameliorated a little with the introduction of specially designed rf pulses designed to give uniform flip angles over a larger proportion of the coil's sensitive volume (see *Surface Coil NMR: Detection with Inhomogeneous Radiofrequency Field Antennas*).

Table 3 Energy sources for muscular activity

<i>Short-term (anaerobic) energy sources</i>	
ATP hydrolysis:	$\text{Adenosine triphosphate (ATP)} + \text{H}_2\text{O} \xrightarrow{\text{myosin-ATPase}} \text{adenosine diphosphate (ADP)} + \text{inorganic phosphate (Pi)} + \text{energy}$
Creatine kinase reaction:	$\text{Phosphocreatine} + \text{ADP} + 0.9 \text{ H}^+ \xrightarrow{\text{creatine kinase}} \text{creatine} + \text{ATP}$
Anaerobic glycolysis:	$\text{Glycogen (glycosyl unit)} + 3 \text{ Pi} + 3 \text{ ADP} \longrightarrow 2 \text{ lactate} + 3 \text{ ATP}$
<i>Long-term (aerobic) sources</i>	
Oxidative phosphorylation:	$\text{Glycogen/Glucose/Free fatty acids/Free amino acids} \longrightarrow \text{NADH}$ $\text{NADH} + 1.5 \text{ H}^+ + 0.5\text{O}_2 + 3\text{ADP} + 3\text{Pi} \longrightarrow \text{H}_2\text{O} + \text{NAD}^+ + 3\text{ATP}$

In vivo spectroscopy is currently only capable of 'seeing' narrow lines produced from long T_2 metabolites, i.e. those in solution in the cytoplasm. These metabolites become MR invisible or only give broad lines, which appear as a hump in the baseline, when in a viscous medium or when bound to the mitochondrial matrix. This is an advantage in that only the cytoplasmic metabolites are important in assessing the muscle energy metabolism during exercise.

In vivo quantification has always been difficult. As a result, many muscle studies report their results in terms of ratios of peak areas. An approximation to quantitation can then be made if appropriate assumptions are made, e.g., the total MRS visible phosphorus concentration or the ATP concentration. This enables estimates to be made of the ^{31}P -containing metabolite concentrations. A common reference method is by comparison with β -ATP concentration. Improved quantitation can be obtained if some form of external or internal standard is used. Internal standards have to be inherent in the muscle under study and thus one method is to collect a ^1H spectrum and to use the water peak as a reference. One problem with this is that the water content of muscle varies, especially during exercise. Assumptions about the water concentration cannot therefore be used. To overcome this, several water spectra at different TR s must be obtained and the true H_2O concentration calculated, but again this is not suitable for exercise studies. An acceptable method is to use an external phantom, often attached to the coil as a reference, and the ^{31}P concentration in vivo is determined by comparison with that from a series of different concentration phosphate solutions external to the limb studied or suitably substituted for the limb after the study.

6 METABOLIC PATHWAYS

Most MRS studies of muscle concern the biochemical pathways (see Table 3) for the supply and utilization of energy. The first reaction to be considered is the hydrolysis of ATP to ADP, catalyzed by myosin ATPase, which produces the energy-driving muscular contraction. Normal muscle only contains a small amount of cytosolic ATP and so can only sustain contractile activity for a very short period of time before fresh supplies of ATP must be made available. These supplies are obtained not from stores of ATP itself but via a reservoir of energy in the form of PCr which is used in the cytosol by the creatine kinase reaction to recycle ADP rapidly back to ATP again. The resulting creatine (Cr) is transported to the mitochondria of the cell where the reverse reaction occurs catalyzed by creatine kinase and Cr is converted back to PCr at the expense of mitochondrial ATP; this is the oxidative phosphorylation reaction or mitochondrial respiration.

Under aerobic conditions, i.e. when the O_2 supply from the blood is maintained, mitochondrial respiration supplies most of the muscles' energy requirements in the form of ATP. This results in production of one-tenth of a mole of H^+ , from carbonic acid, per mole of ATP. When the energy demand exceeds the mitochondrial capacity or when anaerobic (ischemic) conditions exist, only PCr and glycogenolysis can supply the ATP for contraction. When anaerobic metabolism takes place, large amounts of lactate are therefore produced from glycogenolysis, giving two-thirds of a mole of H^+ per mole of ATP leading to a large decrease in intracellular pH.¹⁸ This fall in pH may

have profound effects on pH-sensitive metabolic processes (see e.g., Table 1). Phosphocreatine hydrolysis consumes protons whereas PCr synthesis produces protons. Fortunately it is easy to measure pH by ^{31}P MRS, and after taking into account the effects of buffering and proton efflux, i.e. loss of protons from the cell, the rate of proton production can be calculated. Thus the effect of pH on ATP fluxes can be allowed for. Furthermore, it is believed that pH affects cross bridge kinetics¹⁹ leading to a reduction in force generation, i.e. fatigue.

7 THE STUDY OF MUSCLE USING ^{31}P MRS

7.1 Estimation of pH

Inorganic phosphate (Pi) in vivo has a pK_a of about 6.75 at physiological pH and exists in an equilibrium between two forms H_2PO_4^- and HPO_4^{2-} . These give rise to two separate phosphate resonances, 2.3 ppm apart, which undergo rapid chemical exchange (10^9 – 10^{10} s^{-1}), resulting in a spectrum containing a single resonance whose frequency depends on the relative amounts of the two moieties. Since the equilibrium between the two forms of Pi is pH-dependent, the chemical shift of the Pi peak can be used as an indicator of pH by measuring its chemical shift either relative to an external standard such as methylenediphosphonate or relative to internal standards such as the pH-insensitive resonances due to the phosphorus PCr peak or the proton water signal. In the normal, resting, human forearm muscle of Figure 2, the chemical shift of Pi from PCr is 5.00 ppm corresponding to a pH of 7.15, whereas during exercise the chemical shift of Pi falls to 4.66 ppm corresponding to a pH of 6.88, due to the presence of lactate. The pH may be calculated from the equation.

$$\text{pH} = 6.75 + \log[(\delta - 3.27)/(5.69 - \delta)] \quad (1)$$

where δ is the chemical shift difference, in ppm, between the Pi and PCr peaks.

7.2 The Buffering Capacity of Muscle

A knowledge of the buffering capacity is necessary for determination of ATP fluxes since the H^+ ions are involved in the equilibria (see Table 3). During the initial part of aerobic exercise the assumption can be made that the proton efflux can be neglected, enabling the glycogenolytic rate to be estimated in the same way as for ischemic exercise. This assumption falls down when the buffering capacity has been exhausted and the pH starts to fall. The cytosolic buffering capacity of skeletal muscle depends on Pi ($\text{pK}=6.57$), bicarbonate ($\text{pK}=6.1$), and other buffers, largely imidazole groups in histidine residues. It has been shown²⁰ that in a closed system where the total CO_2 is constant (e.g. during ischemia) the buffer capacity β is given by:

For Pi:

$$\beta = 2.3 [\text{Pi}] / \{ [1 + 10^{(\text{pH} - 6.75)}] [1 + 10^{(6.75 - \text{pH})}] \} \quad (2)$$

where β is measured in slykes (i.e. mmol L^{-1} per pH unit).

For bicarbonate:

$$\beta = 2.3 S p\text{CO}_2 10^{(\text{pH}-6.1)} / \{ [1 + 10^{(\text{pH}-6.1)}] [1 + 10^{(6.1-\text{pH})}] \} \quad (3)$$

where S is the solubility of CO_2 . Taking $p\text{CO}_2$ as 5 kPa and S as $0.3 \text{ mmol L}^{-1} \text{ kPa}^{-1}$ then at its resting pH in closed muscle β is less than 5 slykes.

For other buffers: $\beta = 20\text{--}30$ slykes; inferred by analysis of ^{31}P MRS data and from measurements in muscle homogenates.²⁰

7.3 Muscle at Rest

Many studies have been performed on resting muscle but these have frequently been hampered by the wide range of physiological states of the muscle under study, largely due to the intrinsic variations in the level of training in the populations under study. One of the first and most important findings from studies of resting muscle has been the observation that the concentration of PCr is consistently higher when measured by ^{31}P MRS than when measured by freeze-clamped needle biopsy.⁸ This is almost certainly due to the rapid hydrolysis of PCr to Pi during the freeze-clamping process and this interpretation can be supported by the observation that the total phosphorus concentration [PCr + Pi] obtained by both methods is approximately the same. No such discrepancies between the techniques have been observed with ATP, possibly due to equilibration of the creatine kinase reaction during the extraction procedures. Most quantitative ^{31}P MRS studies on resting muscle have relied not on true quantitation, but on the assumption that the ATP levels are reasonably constant. This assumption requires care as there is evidence that changes in the resting levels of metabolites depend on the prior history of the muscle. If the muscle has been involved in exercise involving lengthening contractions,²¹ the PCr/Pi ratio is significantly reduced up to 1 h after exercise; the reduction continues with the ratio reaching a minimum at 1 day post-exercise and remaining low for between 3 and 10 days postexercise. Similarly, abnormal spectra have been reported for up to 2–3 days after short-term exercise, even when no muscle fiber damage is thought to have occurred. Much evidence is now accumulating to show that type I and type II fibers have different PCr/Pi ratios, with type II fibers having elevated PCr and ATP compared with type I. The resting ratios and changes discussed above may be related to the different fiber-type ratios found in normal subjects.²²

7.4 Exercise and Fatigue

While much information about muscle energy status can be obtained at rest, it is during exercise that the most dramatic changes are seen owing to the high metabolic exchanges associated with muscular activity. Particular interest lies in the study of individuals with defects of metabolism, which can give information about metabolic processes not normally accessible. This is discussed further in Section 8. Metabolic requirements may be determined at various workloads and metabolic processes may be related to physiological changes in function. Muscle fatigue, the decline in force or power output with prolonged activity, has received much attention in this respect, but is complicated by the type of muscular activity

undertaken and the many cellular physiological factors that appear to be interrelated with the chemical changes taking place. For this reason, and the importance of maintaining and improving muscle performance in sports and disease, the various known mechanisms contributing to fatigue are described below.

The central contribution to fatigue can be measured by comparing force output between alternate periods of voluntary contractions with that produced from electrical stimulation of a peripheral nerve. If the voluntary force output falls more than the stimulated force output the difference is due to fatigue of central motor control mechanisms rather than of the muscle itself.²³

Except in the rare neuromuscular disease myasthenia gravis, fatigue due to failure of the neuromuscular transmission is rare. Much of the research of the last half century in this field has been directed toward gaining an understanding of the extent to which impaired energy supply or electromechanical coupling failure is the dominant problem in a particular form of muscular activity.^{24,25} Fatigue of the muscle itself can be classified according to the response to different frequencies of electrical stimulation. Fatigue that is produced more with high-frequency electrical stimulation (HFF) occurs in myasthenia gravis. Low-frequency fatigue (LFF), in which there is selective impairment of force generation at low frequency, i.e., reduced 20:50 Hz force ratio, can occur for a long time after ischemia²⁶ or an eccentric muscular contraction²⁷ when force generation at high frequency has recovered.

From the energetics point of view HFF and LFF can be distinguished by the fact (from needle biopsy and MR studies early in recovery from severe ischemic exercise) that with HFF, recovery of force may occur before full recovery of PCr/ β -ATP (or Pi/PCr), due to rapid recovery of membrane excitation (compound muscle action potential; CMAP). With LFF, force is still reduced 1 h after exercise when CMAP and PCr/ β -ATP have recovered.²⁸

7.4.1 ATP Turnover in Ischemic Exercise

In ischemic (anaerobic) exercise (i.e. when the blood supply to the muscle has been occluded), ATP is produced from two sources, the hydrolysis of PCr catalyzed by creatine kinase (= PCr depletion) and glycogenolysis, the breakdown of glycogen to lactic acid.²⁹ Knowledge of [PCr] and pH can be used to estimate the rate of ATP synthesis. Since decay of the PCr peak can be measured directly, the rate of ATP synthesis from the hydrolysis of PCr (D) can also be measured directly:

$$D = -\delta[\text{PCr}]/\delta t \quad (4)$$

Hydrolytic ATP synthesis also results in a net proton consumption at the rate:

$$\text{net proton consumption} = D/[1 + 10^{(\text{pH}-6.75)}] \quad (5)$$

The production of ATP via glycogenolysis (L) can be estimated from the effect of lactic acid production on pH. Since during ischemic exercise protons cannot escape from the system, glycogenolysis (from glycosyl units) produces 2 mol of lactic acid thereby releasing 3 mol of ATP.²⁹ Thus:

$$L = (3/2)\{D/[1 + 10^{(pH-6.75)}] - \beta\delta pH/\delta t\} \quad (6)$$

where β is the cytosolic buffering capacity of the muscle (derived as above). Since the total rate of ATP synthesis (F) is:

$$F = D + L \quad (7)$$

the total turnover of ATP is:

$$F = D + (3/2)\{D/[1 + 10^{(pH-6.75)}] - \beta\delta pH/\delta t\} \quad (8)$$

7.4.2 ATP Turnover in Aerobic Exercise

In aerobic (oxidative) exercise ATP is produced from PCr and the oxidative synthesis of ATP in the mitochondria. As before, the rate of depletion of PCr and thus the rate of hydrolytic ATP production is readily accessible by MRS. However the presence of oxidative ATP synthesis and the fact that the system is no longer closed, i.e. there is a net efflux of protons from the cells, complicates the assessment of total ATP production. One strategy has been to compare aerobic with ischemic exercise, making use of the power output relationships derived from graded ischemic exercise to provide the 'missing data' from aerobic exercise studies at the same power output.

At the start of aerobic exercise, proton efflux can be neglected and the glycogenolytic rate estimated as for ischemic exercise. At the end of ischemic exercise, when the pH is falling, estimates of glycogenolytic ATP synthesis rates must be corrected for the large proton efflux from the system. This can be done by assuming the proton efflux rate has a linear relationship to pH and [PCr] and thus can be inferred from the initial phase of recovery from exercise.

7.5 Recovery

The study of postexercise recovery provides an opportunity of studying the kinetics of recovery of muscle metabolites, and in particular it can be used to provide information on the pH-dependence of proton efflux, which can also be applied as a correction during the analysis of aerobic exercise.³⁰ After the completion of exercise, the accumulated ADP continues to stimulate mitochondrial respiration to resynthesize ATP; as a consequence, the cytoplasmic PCr pool is replenished through the creatine kinase equilibrium. The PCr replenishment during recovery from exercise has been shown to depend entirely on mitochondrial respiration by the absence of any metabolic recovery when the muscle is made ischemic after exercise by rapid inflation of a sphygmomanometer cuff.³¹ Thus, we can consider the rate of PCr resynthesis to be a good index of mitochondrial function.³²

The recovery of PCr after exercise appears to follow an exponential time course and experimentally is usually treated as such although it has been shown to be biphasic,³³ showing an initial rapid rise followed by a much slower rate of recovery back to resting level. The rate of PCr resynthesis is dependent on the extent of intracellular acidosis, which in turn depends on the work rate during exercise. The final rate of PCr recovery is dependent on the rate of pH recovery and a direct linear relationship has been shown between the value of intracellular pH at the end of exercise and the rate of PCr recovery.³⁴

Figure 3 A comparative ^{31}P NMR exercise study of a patient with phosphofructokinase deficiency and a normal subject

At the end of exercise, intracellular pH continues to fall until a minimum which, depending on the work rate during the exercise, occurs approximately 1 min after the end of the exercise period. The higher the work rate the later pH recovery begins (see Figure 3). The mechanisms that control intracellular pH are not well known though it is likely that active transport mechanisms are involved.³⁵

During recovery [Pi] generally mirrors [PCr]. The Pi accumulated during exercise is transported into the mitochondria where it is used in the phosphorylation of ADP. Like PCr, Pi recovery is biphasic.³⁶ After the end of exercise and during the period in which pH is still falling Pi recovery is fast. Subsequently, as the pH recovers, Pi recovery slows down, and [Pi] decreases to undetectable levels for several minutes before it again reappears and recovers to resting levels. During this time a temporary decrease in the total [PCr + Pi] occurs, which otherwise remains constant throughout exercise. When exhaustive exercise has been carried out, such as to show a reduction of [ATP], e.g. strenuous aerobic exercise, then all recovery processes are substantially impaired.³⁷

8 STUDIES OF MUSCLE DISEASE

Much of what is known about muscle energy metabolism in disease has come from needle biopsy studies. MRS affords a noninvasive approach to the study of metabolism in disease, but the diagnostic value of MRS in muscle is still yet to be

Table 4 Diseases studied by MRS of skeletal muscle (after Barbiroli³⁹)

Disease	Nucleus	Cause or defect	Conclusions from MRS	Ref.
Congenital heart disease	³¹ P	Impaired O ₂ cyanosis	Resting pH and Pi elevated; abnormal PCr depletion and acidification during exercise; prolonged recovery times	40
Duchenne/Becker dystrophy	³¹ P, ¹ H	Inherited lack of dystrophin	Progressive replacement of muscle tissue by fat; high resting Pi/PCr ratio and slightly alkaline pH; PDE peak increases with age; altered energy metabolism in carriers	41–43
Mitochondrial myopathy	³¹ P	Various enzyme defects	Abnormal transfer function: slow recovery of PCr after exercise	44,45
Encephalomyopathy	³¹ P	Mitochondrial enzyme defects	Abnormal transfer function and slow recovery of PCr and pH; abnormal brain energy metabolism	46,47
Glycogenosis	³¹ P	Phosphofructokinase deficiency	Limited acidosis, abnormal build up of PME peak during exercise	48,49
		Phosphoglycerate mutase	Limited acidosis and abnormally raised PME peak during exercise	50
McArdle's disease	³¹ P	Myophosphorylase deficiency	Lack of acidosis during sustained aerobic or ischemic exercise	51,48
Sickle cell anemia	³¹ P	Muscle ischemia	Reduced total ³¹ P compared with normals	52
Malignant hyperthermia	³¹ P	Anesthetic-induced hyperthermia	High resting Pi/PCr ratio; slow post-exercise recovery of PCr/Pi ratio	53
Peripheral vascular disease	³¹ P	Relative ischemia	Acid shift and a fall in PCr/Pi with exercise	54

shown. The advantage of MRS here is in continually providing information of metabolic levels during exercise (whereas repeated biopsy samples were previously required), although resting spectra can provide valuable metabolic information in certain myopathies such as in dystrophy³⁸ and muscle injury.²¹ The question of whether metabolic abnormalities are secondary to other disease processes is becoming of increasing interest clinically in view of the consequences of disease with respect to muscle pain, performance, and fatigue. Some examples are shown in Table 4. A further application has been to study the effects of therapy, for example, in altering muscle energetics, where enzyme defects have limited the energy supply for contraction, such as glucose infusion in McArdle's disease (myophosphorylase deficiency in which glycolysis is impaired),⁵⁵ drug trials in Duchenne dystrophy,³⁸ and the consequences of insulin infusion on phosphate metabolism.⁵⁶

The early applications of MRS in disease, in particular to patients with clear metabolic defects, provided a novel means to study the normal physiological mechanisms limiting exercise. Such patients can be considered to represent 'Nature's experiments' allowing examination of metabolic processes under conditions that would normally not be possible in human

muscle. McArdle's disease⁵⁷ represents an example where a defect in metabolism may manifest itself as a failure of membrane excitation, highlighting the importance of glycolysis for the maintenance of membrane excitability. No lactate is produced in these individuals and hence no acidic shift in the Pi peak occurs, making it possible to measure initial rates of PCr resynthesis and K_m for ADP control of oxidative phosphorylation.⁵¹ Figure 3 illustrates the metabolic changes seen during exercise in a patient with phosphofructokinase deficiency,⁵⁸ which is arguably a more significant metabolic defect than McArdle's disease, in that oxidation of blood-borne glucose is not possible. Accumulation of fructose 6-phosphate traps Pi resulting in a relatively small rise in Pi, and again no change in pH occurs. In these patients fatigue occurs rapidly, but this cannot be attributed to Pi or H⁺.

Another group of the metabolic myopathies is represented by the mitochondrial abnormalities. Those patients affected show abnormalities in oxidative phosphorylation and consequently a high Pi and low PCr,⁵⁹ and slow PCr resynthesis.^{60,61} A number of these patients have been studied with various defects in mitochondrial function, with slowed PCr and ADP recovery, although the most reliable indication comes from the resting spectrum.

Abnormalities in MRS parameters in Duchenne muscular dystrophy have been discussed earlier (see Section 5). The question of whether there is a reduction in energy state of the dystrophic tissue has been difficult to answer owing to the increasing proportion of muscle tissue replaced with fat and connective tissues as the disease progresses,³⁸ and highlights an inherent problem in acquiring a signal from an inhomogeneous tissue. Attempts to correct the acquired phosphorus signal by dilution effects from noncontractile tissue have been made from biopsy samples and indeed several studies have shown a reduced PCr/ATP ratio in dystrophic muscle. Moreover, a reduction in PCr/Pi ratio suggests impairment of mitochondrial function⁶² which is likely to be secondary to the dystrophic process, probably owing to disuse of the muscle, rather than contributing to the damage process, as greater changes are seen in patients with enzyme defects in whom histological evidence of damage is not apparent. Indeed, ³¹P MRS has been reported to be sufficiently sensitive to show abnormalities in metabolism in patients with minimal or no muscle weakness.³⁹

The most marked changes in muscle metabolism demonstrated in disease are probably secondary in origin, particularly where impairment of blood flow is evident. Examples include peripheral vascular disease,⁵⁴ sickle cell anemia,⁵² and congenital heart disease.⁴⁰ It is likely that many more disease states where some degree of fatigue or muscle impairment occurs may also demonstrate abnormalities in metabolism of muscle.

Although MRS has found application in the study of muscle disease for purely scientific purposes, it has yet to find any great application as a routine diagnostic test for muscle disease. This is primarily due to the specialized nature of the MRS examination and the great expense involved when many less expensive procedures are available, e.g. needle biopsy, followed by chemical and genetic analysis. Furthermore, these other procedures are capable of providing information on a greater range of metabolites or gene products than is currently possible by MRS. There is little doubt however that MRS will continue to provide a useful tool for the scientific elucidation of muscle biochemistry in the future, particularly when combined with the use of labeled compounds such as ¹³C-labeled glucose as tracers.

Biographical Sketches

Peter A. Martin. *b* 1954. B.Sc. (Loughborough), Ph.D. (Dunelm). Applications scientist at Oxford Research Systems Limited, 1980–85. Operations manager of Liverpool University's Magnetic Resonance Research Centre 1986–present. Research interests include the applications of neural networks to spectral analysis, proton spectroscopy of the brain, and the quantitation of muscle physiology via MRI and MRS.

Henry Gibson. *b* 1961. B.Sc. (Liverpool), M.Sc. (King's College, London), Ph.D. (Liverpool). Honorary nonclinical lecturer in medicine, Research interests; quantification of muscle physiology via MRI and MRS and ultrasonography of muscle.

Richard H. T. Edwards. *b* 1939. B.Sc., M.B., B.S., Ph.D. (London), F.R.C.P., Codirector of the Jerry Lewis Muscle Research Centre, Royal Postgraduate Medical School. Honorary Consultant Respiratory Physician, Hammersmith Hospital; Professor of Human Metabolism, Hospital Medical School and Head of Department of Medicine, University College, London; Professor and Head of Department of Medicine, University of Liverpool, 1984–present. Director, Magnetic Resonance Research Centre, 1986–present.

Skeletal Muscle Evaluated by MRI

James L. Fleckenstein

University of Texas Southwestern Medical Center, Dallas, TX, USA

1 INTRODUCTION

Clinical evaluation of skeletal muscle has long been hampered by difficulty in assessing the morphology and functional integrity of skeletal muscles. Proton magnetic resonance imaging (MRI) represents a major advance in the diagnosis and management of patients with muscle disease by probing beyond the relatively bland surface of skin to identify focal muscle structural lesions, to determine their extent, and to characterize their composition, and guide invasive procedures and monitor therapies. The purpose of this chapter is to review advances made by MRI in understanding the quality of muscle in health and disease.

2 MR TECHNIQUES

MRI is used to examine patients' muscular anatomy non-invasively and determine which muscles are abnormal in size and shape. MRI further characterizes the quality of muscle by discriminating between the mesenchymal alterations of muscle fat and edema, depending on the pulse sequences used.¹⁻⁴ Fat is detected on T_1 -weighted images (short TR , short TE) by high signal intensity due to its short T_1 time constant. Because fat has a long T_2 time constant, it also manifests high signal intensity on T_2 -weighted (long TR , long TE) sequences.

Increased tissue water leads to increased spin density and elevated T_1 and T_2 relaxation times; hence, muscle edema is detectable using MRI.^{1,2} The long T_1 can be manifested by decreased signal intensity on heavily T_1 -weighted spin echo images. However, in cases in which the sequence is also sensitive to changes in proton density and T_2 , the change in T_1 is frequently not sufficient to result in a net change in signal intensity.²

Using conventional T_1 -weighted and T_2 -weighted spin echo sequences, difficulty is sometimes encountered in differentiating intramuscular fat from edema, especially when they coexist. This is because both edema and fat are hyperintense to muscle on long TR /long TE sequences. This accounts in part for why fat-suppression techniques improve detection of muscle edema.

Multiple fat suppression sequences have been developed that improve detection of muscle edema.¹⁻³ One of these employs an inversion pulse that nulls signal from tissue having a T_1 time equal to that of fat [short inversion time inversion recovery (STIR)]. STIR has the additional advantage of producing heightened lesion conspicuity due to additive effects to signal intensity caused by edema-associated increases in lesion spin density and T_1 and T_2 times.³ Other sequences employ fre-

quency selective pulses to null the fat signal. These techniques generally require a longer TE to achieve the same degree of lesion conspicuity as STIR sequences at the same TR . Important from a financial perspective, a variety of fat-suppression sequences can be incorporated into fast scan techniques, so that high sensitivity to muscle edema can be realized with short scan times. This makes muscle imaging an economically viable, as well as informative, application of MRI.

3 NORMAL MUSCLE ANATOMY AND PHYSIOLOGY

Like computerized tomography and ultrasound, MRI aids physiological studies of muscle size by providing quantitative morphological data regarding the mass of muscle performing work. While cross-sectional area (CSA) has most frequently been used for this purpose, the safety and high spatial resolution of MRI allow for accurate determinations of muscle volume, eliminating errors inherent in modeling volume estimates from single CSA measurements. Incorporation of the muscle fiber pennation angle into estimates of size has further defined morphological determinants of muscle strength.⁵ The ability of MRI to accurately define muscle fascicle architecture also enhances MRI assessment of muscle morphology.⁶ A variety of these techniques has been used to monitor changes in muscle volume during training⁷ and detraining.⁸

Compositional alterations of muscle that can potentially be quantitated with MRI include fiber type, water content and compartmentation, and fat content.⁹⁻²⁵ MRI of muscle fiber type has been studied in both animals and humans, although with conflicting results. In rat soleus muscle, which is nearly all type I (slow twitch, oxidative) fibers, T_1 and T_2 relaxation times are longer than in gastrocnemius muscle, which has a greater proportion of type II (fast twitch, glycolytic) fibers. This difference correlates with a greater extracellular water content in the soleus muscle.⁹ Muscles having such markedly disparate fiber type proportions can easily be differentiated from other muscles on MRI (Figure 1).² Although human muscle has much less variability in fiber type proportion than does animal muscle, a study in humans indicated that the percentage of type II fibers positively correlated with T_2 times.¹⁰ This result is the opposite of what would be predicted from the animal data and so additional studies are needed to determine the accuracy and validity of this MRI application.

MRI measurement of muscle water content can be applied not only to studies of fiber typing, but also to changes that occur as a result of muscular contraction,¹¹⁻²² diuresis,¹¹ and denervation atrophy.^{23,24} As an example, the effects of exercise on the MRI appearance of exercise muscle will be examined in detail. During low-intensity muscular contractions, increases of muscle water primarily occur in the extracellular space; during maximal intensity exercise small increases also occur in the intracellular water space.²⁶ These changes in muscle water content/compartmentation are associated with transient increases in muscle spin density and T_2 times, while T_1 times are relatively less affected.¹² Interestingly, postexercise hyperemia is neither required^{12,13} nor sufficient¹⁴ for the effect to be observed (Figure 1). Animal studies suggest that increases in muscle extracellular water content underlie an increase in the

Figure 1 Effects of fiber type heterogeneity and ischemic muscle contraction visible by MRI. Coronal 2000/60 images of rabbit thighs before (a) and after (b) ischemic muscle stimulation. Note on the prestimulation image that a single muscle (semitendinosus, arrows) has a higher signal intensity than nearby muscles. This is a normal finding in this breed of rabbit and reflects a high proportion of oxidative fibers. After stimulation of the left sciatic nerve, signal intensity increases markedly within the left lateral thigh muscles (arrowhead). Because aortic ligation and death preceded the stimulation, blood flow could not have contributed to signal intensity changes in the stimulated muscles, supporting data in humans that blood flow is not critical in mediating transient MRI changes of signal intensity due to exercise. (Reproduced by permission of the Radiological Society of N. America from J. L. Fleckenstein, R. G. Haller, L. A. Bertocci, R. W. Parkey, and R. M. Peshock, *Radiology*, 1992, **183**, 25)

number of proton spins having long T_2 decay times.^{9,11} This has led some investigators to propose that an increase in this water space is the primary determinant of the changes visible on MRI.^{12,13,15} A role for changes in intracellular water content has also been proposed¹⁶ and debated.¹² These MRI-visible alterations in muscle water are speculated to result from increased muscle osmolality due to accumulation of lactate and other ions which cause osmotic shifts of water between intracellular and extracellular water compartments. This conclusion is supported by absence of the normal postexercise muscle T_2 variations in patients in whom muscle lactate accumulation is absent due to defective muscle phosphorylase (glycogenosis V, McArdle's disease)¹⁴ and by a high correlation between the magnitude of T_2 change and fall in pH in healthy volunteers.¹⁷

Magnetization transfer contrast techniques, exploiting selective saturation of a pool of 'bound' water protons, were applied in two studies to improve the understanding of water compartmentation during MRI of exercise in humans.^{15,18} However, the studies provided conflicting results and conclusions. Another area of apparent controversy regards changes in the T_2 time as a function of work performed. While some studies suggested that T_2 increases in direct proportion to work intensity, the linearity of this relationship has been questioned.¹⁹ Taking these data together it is likely that T_2 varies linearly with work in some regimens but not in others. Recognition that a limit exists in the magnitude of T_2 response (~30%)¹⁹ suggests the existence of a limit to the amount of water that muscle can imbibe from the vasculature during exertion and/or to the magnitude of changes of muscle water compartmentation/binding that can occur during exercise.

Figure 2 Finger-specific components of the flexor digitorum superficialis. Four discrete parts of this muscle can be demonstrated by selective exercise of individual fingers. From left to right are the index, long, ring, and small components of the flexor digitorum superficialis at the mid-forearm. The bones are the radius and ulna. (Reproduced by permission of Raven Press from J. L. Fleckenstein et al.²)

Although the precise mechanism(s) involved in exercise-induced changes in muscle relaxation times during exercise remains unknown, the changes in image contrast between strongly recruited muscle and less active muscle have been exploited in a number of interesting practical applications: diagnosis of disorders of muscle energy metabolism;¹⁴ chronic exertional compartment syndromes;²⁰ identification of muscle recruitment patterns relevant to MR spectroscopy studies of exercise (Figure 2);^{21,22} assessment of manufacturers' claims of muscle recruitment patterns using commercially available exercise equipment (Figure 3).

4 MRI OF MUSCLE PATHOLOGY

MRI has been applied to the evaluation of a broad range of neuromuscular and orthopedic muscle disorders. One of the critical issues that faces a clinician evaluating a patient with neuromuscular disease is determining whether the disease is primarily neurogenic or muscular in origin. This is of particular importance in pediatrics because patients with spinal muscular atrophies (SMA) may present with similar clinical findings to patients with muscular dystrophies, particularly of the Duchenne type (DMD). Early attempts to differentiate SMA from DMD employed ultrasound of the extremities and reported that in SMA the overall volume of muscle was decreased, compared with that of subcutaneous fat.^{27,28} As an additional diagnostic clue, MRI has disclosed selective sparing of specific muscles in DMD, particularly of the gracilis, semimembranosus, and sartorius.^{25,29} A more recent study sought to distinguish SMA of the Kugelberg-Welander type (KW) from DMD.³⁰ It was reported that in KW, muscle deterioration tended to be more diffuse than in DMD and the previous finding of generalized muscle atrophy in SMA was corroborated. A tendency toward relatively selective involvement of type II muscles in DMD was also observed. While more work needs

Figure 3 MRI of 'fly' exercise. Using a commercially available exercise device this healthy subject performed arm abduction against resistance within 1 min of scan acquisition. Note that the pectoralis major (arrowhead), subscapularis (curved arrow), and coracobrachialis (small arrow) are strongly stressed while the pectoralis minor is relatively unstressed (arrow). Therefore, the device does not stress the pectoralis group homogeneously, despite claims of the manufacturer to the contrary

Figure 5 Muscle atrophy and hypertrophy in muscular dystrophy. Symmetric, proximal diminution in muscle volume is evident on a 500/30 sequence. Note sparing of the gracilis (g) and sartorius (s). (Reproduced by permission of Raven Press from J. L. Fleckenstein et al.²)

to be performed to assess the capability of MRI to distinguish between neurogenic and primary muscle diseases, results to date indicate that MRI may be helpful in this distinction.

Muscle dysfunction that results from peripheral neuropathy has also been evaluated with MRI.²⁴ MRI was found able to detect edema-like changes in muscles affected by traumatic or compressive peripheral nerve lesions (Figure 4). These changes were anticipated based on results from an animal study in which proton relaxation times were shown to be prolonged in denervated muscle due to fiber atrophy and a resultant increase in the extracellular water space.²³ Like electromyography, MRI was limited in its ability to detect muscle abnormalities in the first few weeks of denervation. On the other hand, denervation

Figure 4 MRI of subacute leg muscle denervation: edema-like change. Lateral collateral ligament injury (arrow, 500/40) (a) and subsequent scar formation resulted in compression of common peroneal nerve (not shown). Note that signal intensity of denervated anterior leg muscles mimics edema, being normal on coronal T_1 -weighted image (arrowhead) (a), and increased on axial T_2 -weighted image (arrowhead, 2000/60) (b) and STIR (arrowhead, 1500/30/100) (c)

was readily visible on edema-sensitive sequences when denervation had occurred prior to 1 month before the MRI scan. While edema-like change dominated the appearance of muscle in the first year of denervation, fatty change of the muscle was observed in more long-standing denervation. Muscle hypertrophy is a relatively rare result of denervation, and while the finding may be prominent in patients with a remote history of poliomyelitis, it may also be observed relatively early after insult to peripheral nerves.²

Unlike disease of nerve and muscle, neuromuscular junction dysfunction, such as seen in myasthenia gravis, has yet to be reported to have an abnormal appearance on MRI, or any other imaging modality. On the other hand, primary myopathies, including dystrophies, idiopathic inflammatory myopathies, metabolic myopathies, and congenital myopathies, display various muscle abnormalities on MRI.^{25,29,31,32} These findings, including edema-like change and fatty infiltration of muscles, tend to be nonspecific in terms of distribution. For example, selective sparing of the sartorius and gracilis is a feature not only of DMD (Figure 5), but also of polymyositis (Figure 6), congenital myopathies,²⁹ and metabolic myopathies (Figure 7). Selective involvement of the same muscles is a feature of some mitochondrial myopathies² but may be seen in centronuclear myopathy. The character of the imaging abnormality is also nonspecific, in that edema-like change on MRI may be seen in denervation, necrosis, and inflammation.² While not pathognomonic for specific disease processes, the MRI abnormalities are useful in directing invasive procedures, such as biopsy.^{31,32} The objective nature of imaging abnormalities can also be used to monitor response to therapy, which is otherwise limited by the subjective aspects of the patients' sense of well being and by limitations in assessing muscular strength.

In the field of orthopedics, muscle injuries are extremely common and include muscle strains and contusions, delayed onset muscle soreness, and chronic overuse syndromes.³³⁻³⁷ Associated injuries and sequelae of injuries are important determinants of the prognosis of muscle injuries. Because MRI is

Figure 6 Chronic polymyositis. The extensive high signal intensity throughout the thigh muscles on 500/30 (a), and 2000/60 (b), images implies fatty change. STIR suppresses signal intensity from fat, while high signal intensity identifies regions of coexistent muscle edema (arrow) (c). Note that muscle edema is easy to identify only with fat suppression. Such edematous areas are of particular interest during biopsy when inflammatory myopathy is suspected. Note sparing of multiple muscles, including sartorius (arrow) (a) and gracilis (arrowhead) (a)

Figure 7 Glycogenosis: T1W (500/30) (a) and T2W (2000/60) (b) images of the thighs in a patient with phosphofructokinase deficiency demonstrate marked replacement of most thigh muscles by high signal intensity fat. STIR (c) suppresses signal intensity from fat, while areas of high signal intensity identify regions of coexistent muscle edema in the vastus lateralis (arrows). Such edematous areas should be avoided during biopsy when glycogenoses are considered because muscle necrosis may produce a small amount of fetal myophosphorylase in patients who usually lack the adult form of that enzyme (McArdle's disease, Glycogenosis V)

sensitive to both muscle trauma and associated abnormalities, it has been aggressively applied to these orthopedic issues.

Muscle strain is defined as an indirect injury to muscle caused by excessive stretch. Although various clinical schemes of grading severity of muscle strains have been advanced, it is acknowledged that clinical evaluation of muscle strains is difficult, even more so than injuries of tendons or bones. MRI aids in assessing integrity of muscles, myotendinous junctions, fascia, and the tendinous unit. MRI identifies edema within and/or around injured muscles, depending on the stage of healing.^{33,34}

The myotendinous junction is frequently the point of rupture and the extent of associated fascial or tendinous tear can be addressed by MRI (Figures 8–10). When a fascial or tendinous tear is small (Figure 8), the injury can safely be managed conservatively. However, when a rupture is complete, or nearly complete (Figures 9 and 10), early surgery may be indicated; a lapse of even a short time may cause an inferior functional result, due to muscle fibrosis and retraction. Fluid collections also frequently accompany strains. These can themselves be a cause of swelling and weakness in the absence of fascial tear. The use of MRI to distinguish focal hematomas from swollen, edematous muscles can guide clinical management; the former may benefit from drainage while the latter are often treated with wrapping procedures for compression and support of the injured area.⁴

Since recurrent muscle strains can devastate elite athletes, it is noteworthy that MRI in muscle injuries can provide information regarding the prognosis of muscle strain. Two studies have reported on MRI findings that are associated with poor outcome. These studies indicated that the occurrence of focal fluid collections (Figure 10), relatively large volume of abnormality (Figure 11) and fibrosis (Figure 12), correlate with either recurrence of muscle strain, delayed convalescent inter-

val, or both.^{35,36} It is interesting that MRI alterations of strained muscles typically persist for longer than any other clinical evidence of injury.^{33,34} One could speculate that reinstitution of exercise in this setting might be harmful to the healing muscle, but this has not yet been studied. A more immediately practical implication of the delayed disappearance of edema from muscle after injurious exercise is that one may detect evidence of previous muscle injury on MRI after the patient forgets the inciting event. This suggests a potential

Figure 8 Important MRI findings in muscle injury: partial tendon tear. Associated injuries to fasciae and tendons are important to quantitate since small fibrous tears may require no operative intervention. Note partial biceps femoris tendon tear (arrow, 600/20) (a) and STIR (b), and the superior delineation of perifascial fluid using STIR. The lesion was conservatively managed. (Reproduced by permission of Raven Press from J. L. Fleckenstein et al.²)

Figure 9 Important MRI findings in muscle injury: complete avulsion. When muscle tearing is complete, myotendinous avulsion occurs. Complete myotendinous avulsion of a juvenile football player's gluteus medius is easily appreciated on the coronal spin density-weighted image (arrow, 2000/30). The patient was treated by immobilization in a body cast for 12 weeks. (Reproduced by permission of Raven Press from J. L. Fleckenstein et al.²)

source of serendipitously observed MRI abnormalities. On the other hand, this radiographic finding may be the only clue to the true origin of the patient's musculoskeletal complaints.⁴

Other sequelae of muscle injury detectable by MRI include muscle calcification and ossification. Calcific myonecrosis is a delayed complication of muscle injury in which progressive calcification of an injured muscle is associated with slow development of a mass lesion of the extremities. This condition is a rare complication but its radiology is well described, allowing for a confident preoperative diagnosis.³⁷ Muscle ossification (myositis ossificans) is also detectable by MRI but its appearance is nonspecific early in its development, mimicking

Figure 11 Important MRI findings in muscle injury: large volume edema. Factors that suggest a longer convalescent period after injury include a large volume of muscle edema, such as in an axial STIR image of an acutely strained rectus femoris muscle (arrow). (Courtesy of S. C. Schultz, Fort Worth, TX)

neoplastic disease. As it matures, ossified muscle may be identified by peripheral low signal intensity, corresponding to the outer zone of ossification (see *MRI of Musculoskeletal Neoplasms*).

5 CONCLUSION

MRI circumvents traditional obstacles in the clinical evaluation of muscle physiology and pathology. MRI detection of muscle size, fiber composition and orientation, and water shifts are promising research arenas in the field of exercise physiology. The high sensitivity of MRI in detecting muscle edema

Figure 10 Important MRI findings in muscle injury: fluid collection. Rupture and retraction of the posterior head of the rectus femoris in an elite kicker with recurrent muscle strain reveals a 'ganglion-like' fluid collection within a portion of the rectus femoris on axial STIR image (arrow) (a), corresponding to fluid collecting between the retracted posterior head of the rectus femoris and its origin (arrows, sagittal STIR) (b). This injury was treated by resection of the avulsed muscle head

Figure 12 Important MRI findings in muscle injury: scar. MRI-visible scar formation in myotendinous tears is associated with recurrence of strains. Scar is characterized by excessive deposition of signal poor tissue and muscle atrophy (arrow). (Courtesy of S. C. Schultz, Fort Worth, TX)

and fat allows improved delineation of the distribution and composition of neuromuscular and orthopedic disorders. This sensitivity can be used to substantiate muscle as the source of musculoskeletal pain, weakness, or stiffness in a broad range of patients and on the basis of positive, objective findings rather than by exclusion.

1 INTRODUCTION

Throughout the history of nuclear magnetic resonance research there has been a push toward the use of higher field magnets for their advantages in signal-to-noise ratio (SNR), spectral resolution, and simplification of the complex multiplet structures present in *J*-coupled spin systems. Although the advantages of high field systems have been demonstrated for use in analytical work and structural determinations, their application to in vivo spectroscopy in humans has been limited by technical demands. Additionally, because of field-dependent changes in the relaxation properties of the molecules being studied, significant methodological limitations have occurred when lower field (1.5 T) approaches have been applied at high field. Recently, the development of new hardware and alternative methodological approaches has enabled these obstacles to be overcome and many of the advantages of in vivo high-field spectroscopy and imaging to be realized.

In this section we will provide a brief summary of the hardware and methodological advances that have led to the realization of the benefits of high field in vivo spectroscopy in humans, and present several examples of their application. The first section will deal with some of the limitations of conventional rf coil design and an alternative approach for the design of large highly homogeneous rf coils. The second section will describe some of the advantages and the limitations of spectroscopy at high field. The final section will summarize the advantages of both anatomical and functional imaging and how performing these measurements at high field when coupled with the correct methodology yields improvements in both contrast, resolution and sensitivity to physiological alterations.

2 HARDWARE LIMITATIONS

Although homogeneous volume rf coils and efficient surface coils for low-field human studies or high-field small animal research are widely available, the performance of these coils becomes very limited as their dimensions approach the wavelength of the rf being applied. For volume coils of the 'birdcage design', self-resonance for head coils may occur substantially before reaching the desired field strength. Because of the propagation velocity in the conductors used in these coils and the length of the current-carrying elements (as a fraction of

the wavelength), phase changes along the conductors can occur that degrade the homogeneity and sensitivity of the rf coil. Although using distributed lumped element approaches can reduce some of these effects, an alternative approach using transmission line segments and a resonant cavity has seen substantial success.

The utility of transmission lines for high-frequency NMR probes has been recognized since the mid 1970s by Schneider and Dullenkopf.¹ As the first 4 T systems became available Barfuss² used capacitively shortened half wave slotted tubes to construct a 170 MHz body coil. Roschmann³ improved on the high-field design by replacing the unshielded lumped element slotted tubes with half wave coaxial transmission line segments. This design minimized the electric field losses, thereby improving the sensitivity and efficiency of the coil. However, these initial coils had no provision for tuning or matching on each subject, thereby prohibiting maximum performance to be achieved under all conditions. Vaughan⁴ has overcome these limitations by providing a capacitively coupled matching network and a tuning mechanism to adjust the capacitance of all of the transmission line segments, permitting in situ tuning and matching.

Initial theoretical predictions of the homogeneity of high-field rf coils suggested that enhanced skin depth effects would cause an attenuation of the rf field resulting in severe inhomogeneities. However, Vaughan⁴ has shown that the effects of dielectric resonance tend to offset these skin depth effects to provide a highly homogeneous rf field within the human head at 4 T. An additional concern is the perturbation of the rf field by the geometry of the head and the differing electrical properties of the layers surrounding the brain. In most cases these effects can be minimized for a typical head by calculating the B_1 field distribution and/or mapping it, and then adjusting the capacitance and inductance of the coil elements to compensate for the inhomogeneity induced by the cranial geometry and electrical properties. Excellent homogeneity is obtained throughout the slice. The high sensitivity of the coil supports 512×512 resolution for this 3 mm slice, yielding an inplane resolution of 0.47 mm (Figure 1).⁵ Recently, using the same design with multiple drive points, a highly homogeneous 8 T head coil has been constructed.⁶

With the improvement in SNR afforded by higher field strengths, there has been renewed interest in performing spectroscopy studies of lower gyromagnetic ratio nuclei, such as ^{31}P and ^{13}C . For purposes of spatial co-registration, ^1H decoupling and/or heteronuclear acquisition methods, special multiply tuned coil systems have been developed. Vaughan has extended the single-tuned cavity resonator design to a double-tuned coil. Specifically, the ^1H and X nuclei are driven 90° out of phase to each other, using alternate elements around the coil.⁷ This design achieves high homogeneity, high SNR, and (because of the high degree of isolation between the ^1H and X nucleus elements) heteronuclear decoupling is readily achieved without SNR loss. Alternatively, for studies investigating peripheral regions, Adrianny has described a combined surface coil with orthogonal quadrature decoupling coils.⁸ Isolation between the surface coil and quadrature decoupling is achieved through manipulation of the geometry between the two coils. When applied to the occipital lobe, the ^1H quadrature decoupling coils provide excellent visualization of the posterior

Figure 1 Axial image (3 mm) of the human brain acquired at 4.1 T using a cavity resonator. The field-of-view is 240×240 mm using a resolution of 512×512 pixels

portion of the head, with relatively homogeneous decoupling throughout the sensitive volume of the surface coil.

3 SPECTROSCOPY

Perhaps the most obvious advantage of performing spectroscopy at high field is the predicted theoretical linear improvement in the SNR with field. This improvement (a factor of 2.7 from 1.5 to 4.1 T) translates into a linear increase in accuracy of the measurement of metabolites, or a reduction in necessary volume size to achieve the same SNR by 2.7 or, alternatively, a factor of 7.3 increase in speed of acquisition for an equivalent volume and SNR. However, reductions in volume size, especially for spectroscopic imaging, provide special challenges with respect to volume misregistration arising from the increased spectral bandwidth and limited rf amplifier power and gradient strength. To achieve these gains, the alterations in relaxation properties (significantly shorter T_2 values of metabolites) must also be addressed in the methods used in data collection. Finally, changes in the J coupling of ^1H metabolites must also be added before improvements in spectral resolution and spectral simplification can be realized.

3.1 Improvements in SNR and Spatial Resolution at High Field

Hoult has previously predicted that the SNR improvement under sample noise dominant conditions should be linear with increasing field.⁹ This improvement has been documented for ^1H spectroscopy where the increase in the SNR for *N*-acetyl-

aspartate (NAA) was found to be increased by a factor of 2.62–3.44 at 4.1 T over that of 1.5 T after corrections for pulse sequence efficiencies, volume sizes, scans and differential relaxation properties.¹⁰ This improvement in the SNR has allowed high-resolution spectroscopic images of human cerebral NAA to be created with an SNR of 32.5:1 from voxel sizes of 0.5 ml (Figure 2), a factor of two smaller than that typically used at 1.5 T. Despite the small spatial extent of the gray matter about the intrahemispheric fissure, the 0.5 ml voxel allows resolution of the alterations in metabolite ratios and content in gray and white matter. Specifically, the elevated total creatine (Cr)/NAA ratio reported in autopsy results¹¹ for gray matter to white matter is easily visualized in the spectra from parietal white and gray matter (Figure 2). The ratio NAA/Cr has been extensively used as a marker for neuronal loss, such that the resolution of these differences has important applications in resolving true neuronal loss from partial volume effects resulting from inclusion of a mixture of gray and white matter. By optimizing the repetition time, echo time, and using frequency selective suppression of the lipid resonances, ultra-high-resolution spectroscopic images can be obtained. Proton spectroscopic images employing volumes as small as $175 \mu\text{l}$ have been acquired using a homogeneous volume head coil and are presented in Figure 3. In these images, the 2–3 mM difference in Cr content between gray and white matter is easily visualized in the Cr spectroscopic image.

Perhaps more significantly, the improved SNR can also be used to improve the spatial resolution of low sensitivity nuclei such as ^{31}P and ^{13}C . Typically, ^{31}P spectra of the human heart are acquired with voxel resolutions of 20 to 80 ml using single voxel localization methods or, more recently, one-dimensional chemical shift imaging.^{12–14} Because of the large voxels acquired in these studies, significant contamination from the myocardial blood pool occurs. Owing to this contamination, corrections for the adenosine triphosphate (ATP) content of the blood pool, based on the 2,3-diphosphoglycerate (2,3-DPG) content are required, before correct myocardial PCr/ATP ratios can be calculated. At 4 T, Menon has demonstrated, using a one-dimensional chemical shift imaging method, that voxels of 8–25 ml can be collected from the human heart that are free of blood pool contamination.¹⁵ Using the increased SNR available at 4.1 T, complete three-dimensional chemical shift images of the myocardial PCr content can be acquired using three-dimensional spectroscopic imaging methods. Displayed in Figure 4 are representative spectra of human heart acquired with a spectroscopic imaging sequence using 8 ml voxels.¹⁶ Evaluation of spectra acquired from the apex, septum, and left ventricular free wall shows that they have minimal contributions from 2,3-DPG (Figure 4). Therefore, quantitative measurements of the regional levels of high-energy myocardial phosphates are possible. Gruetter has used the enhanced sensitivity at 4 T to acquire ^{13}C spectra of human brain from volumes of 72 ml using a 72 min acquisition.¹⁷

3.2 Relaxation Properties at High Field

Many ^1H localization methods have relied heavily on long spin echo sequences ($TE = 136$ – 272 ms) to achieve good water and lipid suppression. These methods have been highly successful and provide good sensitivity through the long T_2 values of many cerebral metabolites at 1.5 T. Frahm has measured the

Figure 2 (a) Proton scout image of the human brain and (b) the corresponding NAA image. The NAA image is acquired from a FOV of 240×240 mm using 32×32 encodes. The echo time (TE) of the spectroscopic image is 50 ms. (c) The numbered locations (1–10) on the scout image correspond to the numbered spectra. The resolved resonances are NAA 2.02 ppm, creatine 3.02 ppm, and choline 3.19 ppm. (Reproduced from Hetherington et al.¹⁰)

Figure 3 A scout image (a), a spectroscopic image of the distribution of creatine (CR) in the selected slice (b), and an overlay image (c), where the blue contours indicate the edges between gray and white matter. (d) An image and three representative spectra (175 μ l nominal volume) and the corresponding locations on the scout image

T_2 values of NAA, Cr, and choline to be 450, 240, and 330 ms, respectively.¹⁸ At 4.1 T the T_2 values of these metabolites become significantly shorter, decreasing by nearly a factor of two to 220, 140, and 190 ms, respectively.¹⁰ Similar values have also been reported by Posse and co-workers.¹⁹ Therefore, significant losses occur at high field when long echo times are used. This necessitates the use of short-echo localization methods such as stimulated echo acquisition (STEAM)²⁰ and/or simple spin echo methods.²¹

Unlike T_2 relaxation, T_1 relaxation times for ^1H metabolites are relatively unchanged. Posse has reported T_1 times of 1.6, 1.6, and 1.2 s for NAA, Cr, and choline, respectively, at 4 T. These values compare well with the T_1 values of 1.45, 1.55, and 1.15 s, respectively, measured at 1.5 T. Therefore, no additional sequence modifications are required for T_1 -based selection or discrimination methods.

Myocardial ^{31}P metabolites show increases in their T_1 values. Menon et al. have measured myocardial T_1 values of ATP and PCr to be 2.7 and 5.4 s, respectively. Therefore, the lengthening of the T_1 at 4 T for ^{31}P metabolites will tend somewhat to offset the SNR gains for equivalent repetition times by causing greater saturation effects. To take full advantage of the SNR gains possible in ^{31}P spectroscopy, methods utilizing partial tip adiabatic excitations²² and/or combinations of homogeneous transmit and surface coil receivers²³ will be of significant benefit.

3.3 Spectral Resolution

One advantage of high-field spectroscopy is the improvement in spectral resolution achievable for J -coupled

Figure 4 Voxels (8 ml) acquired from a three-dimensional spectroscopic imaging sequence applied to the human heart. The resolved resonances are for PCr, (0 ppm), α -, γ -, and β -ATP (–2 to –18 ppm) and inorganic phosphate (Pi) + 2,3-DPG (5–10 ppm) (Reproduced from H. P. Hetherington, D. J. E. Luney, and J. T. Vaughan, *Magn. Reson. Med.*, 1995, **33**, 427.)

resonances. This effect stems from two factors, the increase in spectral dispersion (in hertz) from the increased field in the presence of a field invariant coupling constant and a simplification of strong coupling for homonuclear coupled ^1H resonances. The advantage of the increased spectral resolution is most

Figure 5 Spectra of a solution of glutamate acquired at 1.5 and 4.1 T

easily seen in the ^1H spectra of human brain. For ^1H spectroscopy, the most dramatic improvement is in the resolution of the C-3 and C-4 resonances of amino acids such as glutamate and glutamine. At 1.5 T, the C-3 and C-4 resonances of glutamate are strongly coupled such that they appear as a broad complex multiplet (Figure 5). However at 4.1 T the C-3 and C-4 resonances experience much weaker coupling such that they resolve into two clearly distinct multiplets. This improved resolution also permits the individual C-4 resonances of glutamate and glutamine to be resolved from each other. Specifically the two most downfield lines of the glutamine triplet are resolved from the two most upfield lines of the glutamate triplet (Figure 6). Therefore, unlike measurements at 1.5 T, where the strongly coupled resonances of glutamate and glutamine show substantial overlap, the individual contributions of these resonances can be clearly determined at 4 T.²⁴ However, as the nature of the coupling changes, so do the amplitudes of the multiplets as a function of echo time. Although echo times of 20–30 ms can be used for detection of amino acids at 1.5–2.0 T,^{25,26} an echo time of 20 ms results in substantial loss in sensitivity at 4.0 T.²⁴ However, Pan has demonstrated that SNR losses in amino acids can be avoided at moderate echo times when using a J -refocused acquisition.²⁷ In this sequence, the effects of J -modulation for coupled spins is reversed by transferring magnetization through a multiple quantum evolution period. Figure 7 shows spectra acquired with a 40 ms TE using the J -refocused sequence from human brain at 4 T.

In addition to the improvement in spectral resolution of amino acids, the increased separation between coupled reson-

Figure 6 Spectrum acquired for a 2.25 ml voxel from human brain at 4.1 T as part of a spectroscopic imaging study using a TE of 15 ms. The two most upfield lines of glutamate (Glu) are resolved from the two most downfield lines of glutamine (Gln). The data set was acquired using 16×16 phase encodes with four phase cycles and a TR of 2000 ms

Figure 7 The *J*-refocused spectroscopic imaging sequence used to acquire a 1 ml spectrum from the occipital lobe. ances at 4 T affords significant advantages for spectral editing sequences. Rothman has demonstrated at 2.1 T that gamma-aminobutyric acid (GABA), the primary inhibitory neurotransmitter in mammalian brain, can be detected using spectral editing sequences.²⁸ However, because of the proximity of a macromolecule resonance and similarity in chemical structure, substantial overlap (60%) between the two resonances occurs in the edited spectrum. At 4 T, as a result of the additional separation in hertz between the coupled resonances of the macromolecule (1.7 ppm) and C-3 GABA resonance (1.9 ppm), this overlap can be reduced to 24% when highly selective inversion pulses are used.²⁹ Use of even more highly selective pulses can reduce this overlap to less than 10%. Use

Figure 8 Spectra acquired from a 13.5 ml volume in the occipital lobe employing a 4.26 min acquisition. Spectrum acquired without (a) and with (b) a selective inversion pulse applied to the 1.9 ppm gamma-aminobutyric acid (GABA) C-3 resonance. (c) The difference spectrum of (a) and (b) displays the characteristic doublet GABA-edited spectrum (outer two lines of the GABA triplet)

Figure 9 Spectra acquired from the hippocampi of a patient with temporal lobe epilepsy and a normal volunteer as part of a spectroscopic imaging at 4.1 T. The data were acquired using a *TE* of 50 ms and a *TR* of 2000 ms. The 240×240 field-of-view was acquired using 32×32 phase encodes with a single acquisition per encode

of these methods has permitted the measurement of acute elevations of brain GABA levels in response to novel antiepileptic drugs in normal controls (Figure 8).³⁰

3.4 Clinical Applications

The impact of the ability to acquire small voxels can be appreciated in the use of ^1H spectroscopic imaging in the diagnosis of temporal lobe epilepsy in patients with intractable seizures. It has been demonstrated by a number of laboratories that ^1H spectroscopy at 1.5–2.0 T provides a sensitive measure of neuronal loss as expressed in NAA content or NAA/Cr ratio measures.^{31–33} However, the small size of the hippocampus (1.5 ml $\times$ 1 ml $\times$ 3 ml) and the complex anatomy surrounding the hippocampus, cerebellar vermis, temporal gray and white matter, and midbrain, with their varying Cr/NAA ratios (0.5–1.33, normal gray matter is 0.7) can obscure measurement of neuronal loss. False positives and negatives can occur when significant amounts of the cerebellar vermis or temporal white matter are included.³⁴ However, the small voxels afforded at 4 T (0.5 ml nominal volume) permit separation of these regions and improve the sensitivity of the detection of epileptic foci. Figure 9 shows typical spectra from the ipsilateral and contralateral hippocampi of an epilepsy patient and a healthy volunteer. The affected hippocampus is identified by the marked increase in the ratio of Cr/NAA.

4 ANATOMICAL AND FUNCTIONAL IMAGING

Previously it has been expected that anatomical images at high field would be degraded by the effects of an increased skin depth effect and the loss in intrinsic contrast by decreasing differences in the T_1 values of gray matter, white matter and cerebrospinal fluid. Ugurbil and colleagues first demonstrated that excellent gray/white contrast could be achieved in the human brain at 4 T using a modified driven equilibrium sequence exchanging the SNR for contrast.³⁵ The sequence uti-

Figure 10 High resolution 3 mm image of the human brain acquired at 4.1 T. The field-of-view is 240×240 using a resolution of 512×512 . The data were acquired with 3 mm slice thickness as part of an eight slice study using an inversion–recovery time of 1000 ms, a TR of 2500 ms, and a TE of 17.5 ms

lized a 90–180–90 sequence to provide an approximate quadratic dependence on T_1 .

More recently it has been demonstrated that excellent contrast can be achieved using a simple inversion–recovery sequence with a gradient echo readout.⁵ Displayed in Figure 10 is a 3 mm 512×512 gradient echo image of a human brain acquired at 4.1 T. Such images display excellent resolution of a number of cerebral anatomical features (caudate head, globus pallidus and putamen). The internal capsule is resolved through the high gray/white matter contrast. Resolution of these sub-cortical structures is important since they are frequently the site of small strokes less than 10 mm in diameter (lacunae). The major groups of the thalami are resolved and correspond to the medial and lateral thalamic nuclear masses. The high spatial resolution and contrast are critical for visualizing the thalamic masses given that the internal medullary lamina, the intervening structure, is approximately 1 mm thick.

Because of the arterial blood flow originating from the posterior aspect of the circle of Willis medial to the temporal lobe, the highest quality coronal images of the temporal lobes are obtained by gating the acquisition to the cardiac cycle. Owing to the strong susceptibility differences in the regions around the temporal lobes and the relatively long echo time used, some degradation of image quality is experienced in the temporal lobe. This can be compensated for in part by using a shorter gradient echo time in the acquisition sequence. Regardless, excellent resolution and detail is observed in the visualization of the hippocampus (Figure 11). Specifically, the parahippocampal gyrus, Ammon's horn with the alveus extending into the fornix, the subiculum, and the overlying superficial medullary stratum are well defined. The reliability of lateraliz-

Figure 11 High-resolution 3 mm image of the human brain acquired at 4.1 T. The field-of-view is 240×240 using a resolution of 512×512 . The data were acquired with a 3 mm slice thickness as part of an eight slice study using an inversion–recovery time of 1000 ms, a TR of 2500 ms, and a TE of 17.5 ms. The data were acquired with a coronal orientation through the hippocampi

ing the focus in temporal lobe epilepsy by MRI will be improved with this level of resolution. Such high-resolution images may also aid in the further study and diagnosis of Alzheimer's disease.

Perhaps the most striking qualitative difference between 4.1 T high-resolution images and those acquired on widely available lower field clinical systems is the visualization of small cerebral vessels in all axial images (Figure 12). With finer slice separation it should be possible to define the majority of the deep cerebral veins. The fine radiation of vessels has not previously been seen routinely *in vivo*. Visualization of such vessels is most demanding of resolution and contrast available at high field. The contrast is most likely related to the deoxygenated hemoglobin present in veins, decreasing the signal against a background of high signal intensity from white matter.

In summary, imaging at 4.1 T depicts the brain with very high resolution, which should allow detection of disease states not heretofore imaged noninvasively. This approach could potentially obviate the need for angiography or biopsy.

The best advantage of high-field imaging is that of the enhanced sensitivity to changes in deoxyhemoglobin, which forms the mechanism for blood oxygenation-dependent (BOLD) contrast in functional imaging.³⁵ The enhancement of field strength is believed to range from linear to quadratic in strength. Thus the small changes that are seen in functional imaging studies (1–5%) can be measured with the highest sensitivity only at high field. This effect has been used by a number of investigators at 4 T to investigate the effects of various paradigms of brain activity on oxygen consumption and delivery and the localization of those effects. The results suggest that valuable insights into brain physiology and psychiatric and various pathological states are on the horizon. The utility of functional imaging at high field will provide a primary driving force for the proliferation of high field systems.

Figure 12 High-resolution 3 mm image of the human brain acquired at 4.1 T. The field-of-view is 240×240 using a resolution of 512×512 . Low-Field Whole Body Systems

Leon Kaufman, David Kramer, Joseph Carlson and Mitsunaki Arakawa

UCSF-RIL, San Francisco, CA, USA

1 INTRODUCTION

MRI is a medical diagnostic modality. As such, it is of value only if it is available to the people who can benefit from its use. Because for most subjects MRI use is not limited by risk–benefit considerations, cost–benefit analysis is becoming the major determinant of use. In cases like this, as the cost of a study decreases, the utilization (and presumably the benefit) increases. Decreasing the costs of MRI requires careful attention to the physics and engineering of the discipline. The major determinant of cost is field strength. By reducing the field strength it becomes possible to use nonsuperconducting magnets. Low-field systems can be sited in smaller rooms, and this further reduces initial and ongoing costs. Other components where significant savings are achieved include rf transmitters and, in some cases, gradient coils. Once the cylindrical magnet configuration can be avoided, the range of suitable low-field magnets includes some that are open. These, in turn, offer opportunities in terms of interventional studies (where low fields have some other practical advantages), and in dealing with difficult or ill patients.

2 PHYSICS OF LOW FIELD STRENGTH OPERATION

As field strength decreases, so does the strength of the NMR signal emitted by the body. Nevertheless, imaging is a complex process that involves many factors. With decreasing field strength, noise from the body also decreases. Chemical shift and susceptibility artifacts decrease, permitting narrower bandwidths and consequent reductions in noise. T_1 shortens^{1,2} and T_2 lengthens,² this increasing signal level during imaging. Motion artifacts decrease, so that the fraction of study time spent on motion reduction can be used for data acquisition, and rf power deposition decreases dramatically. Radiofrequency pulses can be tailored to improve section profiles and, more importantly, the hazard from rf heating is all but eliminated. At lower field, absolute magnetic field inhomogeneities get smaller (for imaging, a magnet with a 30 ppm homogeneity specification at 500 G is equivalent to one with a 1 ppm specification at 1.5 T). This, and decreased susceptibility effects, permit the use of gradient echo techniques where spin echoes may need to be used at higher fields.³ The shortened T_1 values favor the use of three-dimensional FT techniques, which can be designed

to provide a wide range of contrast capabilities with good signal-to-noise ratios.^{4,5} Furthermore, for water-elevating lesions, for the same sequence, contrast will typically be higher at the lower field. This is due to two factors: the shortened T_1 of tissues permits contrast from T_2 and proton density $N(H)$ changes to become visible at shorter TR values;⁶ and the change in T_1 and T_2 with water content is larger the lower the field.^{1,2} The impact of these effects will depend on the type of study being performed, but, in general, for the same volume resolution and coverage, and for equivalent contrast, there will be a signal-to-noise ratio difference of 2–3 over a range of field strength of a factor of 25.

3 MAGNETS FOR LOW-FIELD MRI

Various choices of magnet are available for low-field development. Resistive magnets were the early choices, but with the advent of practical permanent magnet designs the latter have become incorporated into the more recent commercially available products. Magnet technology involves two basic components: the driver and the core of the magnet. The driver provides the motive force that establishes the magnetic field. Three types of driving technology are available in the marketplace: resistive, permanent, and superconducting. The Earth's magnetic field is a fourth source that has been discussed in the literature but has not become commercially available. The core is the medium upon which the driver acts. Because a patient has to be able to be located in the magnet (a prerequisite for reimbursement), all magnets have at least a portion of their field in air. Air-core magnets are those where all of the core is air. These may have a return path (the region outside of the core where the magnetic field lines close) that is either air or iron. Iron-core magnets have, except for the patient volume, iron paths both for the drivers to act on and as return paths. The relative merits of these approaches to magnet design are discussed below.

3.1 Drivers

3.1.1 Resistive Drivers

In a resistive driver, a current is established on a good conducting material, typically copper or aluminum (during the Manhattan Project silver from the US reserves was used for huge magnets for uranium separation, since copper and aluminum were needed for armaments). The conductor is at or near room temperature, so it offers resistance to the flow of current. This resistance has two effects: power has to be used to maintain the current flow and attendant magnetic field, and heat is generated in the conductor through resistive losses. Consequently, water needs to be used to extract this heat. In addition, the stability of the field depends on power-supply stability, stability coming at a price.

The advantages of the resistive driver is that the technology is well known and understood, and the entry is easy, since a great deal of expertise exists or is easily acquired by a company. The disadvantages are high power consumption, large cooling demand, a large conductor mass, and its consequent weight. When an iron core is used, the larger mass of conduc-

tor forces an increase in the physical size of the core, which then results in further weight increases.

3.1.2 Permanent Drivers

In a permanent magnet, the field originates in blocks of permanently magnetized material. Currently available are ferrite magnets for low-field operation and Neomax (a rare earth alloy) for higher fields. The attractive aspect of permanent magnet drivers is that they are totally passive, requiring no added services such as electricity, cryogenics, or cooling. The disadvantages are that there is a very steep cost/field curve, especially when rare-earth materials are needed for higher fields; in addition, the weight of the permanent magnet material adds to the weight of an iron core.

For the higher field units, a potential problem is that the magnet cannot be discharged in an emergency.

3.1.3 Superconducting Drivers

There are materials, generically known as superconductors, that if kept at a sufficiently low temperature lose all resistance to current flow. In typical magnets for MRI, this temperature has to be well below 10 K, that is, under 10°C above absolute zero. A convenient way to achieve this is by the use of liquid helium, which has a temperature of near 4 K. The liquid boils away through heat leaking into the magnet from room temperature. Because of cost, it is desirable to minimize the boil-off of the helium. One method used in the early years of commercial MRI was to use a surrounding container with liquid nitrogen, which has a temperature of 77 K, intermediate between the helium and room temperatures. This, of course, adds liquid nitrogen consumption to the services needed for magnet operation. Later, electrical shield coolers were added to magnets to replace the liquid nitrogen 'shield'; these coolers usually reached temperatures well below 77 K, thus improving the shielding effect. Also, recirculating coolers that reliquefied the vented helium gas were added to some magnets, even though in the USA this was not usually economic because of the relatively low cost of liquid helium.

More recently, electrical coolers that reach 4 K have become commercially available. This opens the way to cryogenless superconducting magnets with low power consumption. It is worth noting that the high-temperature superconducting materials that a few years ago were promoted as permitting magnets cooled by liquid nitrogen have yet to provide the performance required by MRI magnets; however, they have found use as superconducting leads, which bring current from the outside to the main windings during magnet charging and discharging.

The advantage of superconductors for MRI is the achievement of relatively higher fields compared with the other technologies, with low weight and modest power consumption. The disadvantage is the need for cryogenics (or, more recently, cryocoolers that can replace cryogenics) and the technical complexity of these systems compared with other drivers, this making entry more difficult. In terms of cost, at a certain field strength crossover point superconductors become cheaper than other drives. Once the midfield range is reached, they have definite advantages in this respect.

3.2 Magnet Core

The driver can be shaped to obtain the desired imaging field and field return path without the aid of significant amounts of iron; this is known as an air-core magnet. Alternatively, the iron can be used for shaping the imaging field and providing a return path; this is an iron-core magnet. Some air-core magnets have an iron return path or shield.

The advantage of air-core magnets is low weight. The disadvantages are inefficient use of conductor, demands on the conductor configuration and manufacturing tolerances (since the homogeneity depends on the conductor), and large fringe fields that require active or passive shielding. All of this, of course, results in increased costs.

Iron-core magnets make more efficient use of the driver, since the iron provides a medium that offers less 'resistance' to the flow of the magnetic field lines. In iron-core magnets fringe fields are relatively small, and homogeneity is determined by the shape of the iron. This places fewer demands on the driver's configuration and tolerances. The main unavoidable disadvantage of these cores is weight.

3.3 Other Factors

There are obviously other nuances about the different drivers and cores that need to be taken into account when designing an MRI system, but the characteristics described above are of a reasonably general nature and not amenable to significant manipulation. Commercially, we have seen the following driver-core combinations become available at one time or another in the lifetime of clinical MRI: (a) resistive, superconducting, and permanent driver air cores, the first two sometimes with iron shielding; and (b) resistive, permanent, and superconducting driver iron core. Iron cores can be 1-(C), 2-, and 4-post designs. Recent magnet assembly technology results in elimination of eddy currents without the need for active gradient coil shielding. The design of these magnets involves tradeoffs among cost, size, weight, gap, homogeneity, fringe field and field strength. Typically, larger gaps, higher homogeneities, smaller fringe fields, and higher field strengths require larger, heavier magnets of higher cost.

4 SEQUENCING FOR LOW-FIELD IMAGING

Sequence development for low-field imaging needs to take into account, and take advantage of, the short T_1 value of solid tissues. Also of importance are reduced chemical shift and susceptibility artifacts. One example involves strategies for the detection of lesions where water content is increased. This is a typical effect seen in tumors, edema, and infarcts. Considering the case where there is no blood, for these lesions $N(H)$, T_1 , and T_2 are all elevated.⁶ In a spin echo sequence the elevation of $N(H)$ and T_2 increases signal, while the elevation of T_1 decreases signal. Thus $N(H)$ and T_2 effects are diluted by T_1 effects. To obtain a lesion that is brighter than the background it is necessary to increase TR to the point that T_1 effects become unimportant. This results in what is misnamed a ' T_2 -weighted' image. In fact, a more accurate measure would be 'not T_1 -weighted'. To achieve this condition reliably, it is

necessary to operate with a TR of at least $2T_1$, preferably 2.5 – $3T_1$. Since T_1 increases with field strength, this means that it is necessary to operate with a longer TR at the higher field. For instance, for brain tissue the increase between 0.064 T and 1.5 T is approximately a factor of 4, from 250 ms to about 1 s for white matter, and from 300 ms to 1.2 s for gray matter. Thus, for a spin echo sequence, the desired lesion contrast is easier to achieve, and is more reliably achieved, at the lower field. This has significant consequences in terms of the signal-to-noise ratio, since shorter TR values can lead to a larger number of data averages for fixed imaging time.

For ‘watery’ lesions, the ability to use short TR values opens an avenue for imaging with three-dimensional FT sequences. The TR that can be achieved in three-dimensional FT imaging is limited by practical considerations of time, since this time increases linearly with the number of slices obtained. If gradient echo instead of spin echo imaging is used, a flip angle smaller than 90° results in a decrease of T_1 effects. Lowering the angle at fixed TR has the same effect as lengthening TR for a 90° angle. Unfortunately, this cannot be carried to extremes, but this process is more effective the larger the TR/T_1 ratio. Thus, from a practical point of view, it is only achievable for short T_1 values, where it is highly effective. Furthermore, to obtain the desired contrast level it is desirable to operate with a relatively long TE , to take advantage of T_2 effects.

Gradient echo imaging (used in conjunction with partial flip angles) is highly sensitive to susceptibility and inhomogeneity effects, this sensitivity increasing with TE and with field strength. At low field the gradient echo technique shows no noticeable artifacts from susceptibility, chemical shift or inhomogeneity artifacts, permitting a late echo ($TE = 53$ ms) with a long sampling window. A relatively long TR value (110 – 145 ms in our case), combined with a flip angle of 12 – 20° , at 640 G, reduces T_1 effects so that the elevated T_2 and $N(H)$ of lesions makes them appear bright, with cerebrospinal fluid (CSF) still being of low intensity⁴ (Figure 1). Thus, the combination of short T_1 and the low inhomogeneity and susceptibility effects that accompany low-field operation permit for this application the use of gradient echo three-dimensional FT imaging, which under these conditions results in signal-to-noise ratios at low fields comparable to those of mid- and high-field systems when taking into account the imaging time and the number of sections obtained.⁴ At this field strength three-dimensional FT imaging is the preferred method for obtaining images of thin sections.⁵ Figures 2 and 3 show a pituitary with section thicknesses of 4.5 and 2.25 mm, respectively.

A hybrid technique consisting of a multislab two-dimensional FT sequence with two-slice encodings within a slab, coupled with partial flip angle gradient echo imaging, has permitted us to develop a sequence that takes advantage of low field operation characteristics and doubles the signal-to-noise ratio over that of conventional spin echo.³ The multislice double echo spin echo imaging technique introduced by Crooks⁷ quickly became the ‘gold standard’ of lesion detection.⁸ At low field it is possible to increase its efficiency dramatically by the following steps:

1. Take advantage of short T_1 values by using a short TR and slice doubling⁹ to maintain high coverage. The shortened

Figure 1 Transaxial view of a patient with multiple sclerosis lesions, obtained at 640 G. Lesions are brightest, and, in descending order of intensity, gray matter, white matter and CSF. Three-dimensional FT gradient echo with $TR = 145$ ms, $TE = 53$ ms, and flip angle = 20°

TR is traded off against increased data averaging to increase the signal-to-noise ratio.

2. Lengthen the echo window.
3. Use gradient reversal instead of rf refocused echoes to reduce dead time in the sequence. This permits the number of slices obtained to be high, even though the windows are long.

Figure 2 Three-dimensional FT gradient echo imaging with $TR = 68$ ms, $TE = 24$ ms, and flip angle = 60° , at 640 G. Section thickness 4.5 mm

Figure 3 As Figure 2, but with a flip angle of 45° and a section thickness of 2.25 mm

4. Take advantage of the gradient reversal echo to use partial flip angle excitations, in order to maximize further the signal-to-noise ratio and the contrast.

Figure 4 (a, b) Spin echo imaging 640 G in a patient with multiple sclerosis; $TR = 2$ s, and $TE = 30$ and 105 ms in (a) and (b), respectively. (c, d) Gradient echo images; flip angle = 60° , $TR = 0.8$ s, and $TE = 20$ and 70 ms in (c) and (d), respectively. The spatial resolution and number of sections are the same for both sequences. The earlier TE values of the set (c, d) reduce contrast, but the display system can be set to display any TE in a real-time basis. Comparing (a, b) and (c, d), the signal-to-noise ratio has essentially doubled, in the latter

Figure 5 Two-dimensional FT, multislice gradient echo images through the head of a subject with white matter lesions. Note the low level of susceptibility artifacts at 640 G

Compared with a spin echo sequence, for equal imaging time and number of slices, this sequence has comparable contrast and twice the signal-to-noise ratio³ (Figures 4 and 5).

A significant benefit is derived in low-field operation from the fact that, while at low field solid tissues have shorter T_1 values, CSF has a T_1 that is constant with field. Consequently, at the short TR where lesion contrast is achieved, the signal from CSF is small. At high field, because TR has to be long, the CSF signal is large, obscuring lesions that may be contiguous with CSF spaces. To summarize, low field strengths offer many advantages for the detection of water-elevating lesions, including increased sensitivity to water changes, the ability to operate with relatively short TR values, and the avoidance of confusing effects from bright CSF.

Figure 6 MRA at 640 G, using phase contrast imaging

Another example of low-field sequencing involves magnetic resonance angiography (MRA). In MRA the clinically most successful techniques take advantage of wash-in effects.¹⁰ The blood entering the volume has not been excited previously and thus produces a great deal of signal following the first one or two excitations.¹¹ Meanwhile, it is desirable to saturate the signal from stationary tissues by the same repeated excitations that produce signal from blood. This saturation is more effective the longer the T_1 , since recovery time is longer. Because high-field operation entails long T_1 values, high contrast between blood and nonmoving tissues is easier to obtain. This permits more flexibility in trading vessel contrast for depth of penetration (field of view) than at low field, where T_1 values are short. For low-field systems, phase contrast angiography becomes an extremely attractive alternative. Figure 6 shows an example.

Imaging of chemical shift is also accessible at low field for protons in water, fat, and silicone, by reconstruction of phase images for three-dimensional FT sequences. We have found this method particularly powerful in searching for extracapsular silicone in breast implant patients.¹² The chemical shift images have the same resolution and signal-to-noise ratio and do not require additional imaging time (Figure 7).

5 SEQUENCES FOR MID-FIELD IMAGING

MRI started as a mid-field technique. Many of the sequences that are currently considered 'routine' were originally developed at mid-field, so contrast characteristics are more familiar. The contrast characteristics of mid-field MRI are closer to low than to high field. For instance, brain lesions are bright while CSF remains of lower intensity; consequently, fluid attenuation inversion recovery techniques (FLAIR) are not

Figure 7 Subject with silicone breast implants. Top row: $TR = 110$ ms, $TE = 40$ ms, flip angle = 45° , magnitude image. Bottom row: phase image from the same data set. At 640 G, silicone and water are nearly out of phase (silicone, bright; water, dark) and fat is intermediate

needed to highlight periventricular lesions (Figure 8). Fat signal gains in relative intensity compared with low field, but inversion recovery and multipoint Dixon techniques make it easier to suppress fat (Figure 9). In gradient echo imaging, water and fat are out of phase at a convenient TE of 10 or 30 ms and in phase at TE of 20 ms. The former results in fast sequences for screening for bone marrow abnormalities (Figure 10). The T_1 of blood lengthens enough to make time-of-flight MRA techniques attractive (Figure 11). Also, CSF is easier to highlight (Figure 12). Single-shot fast spin echo imaging results in effective imaging of long T_2 tissues, principally CSF. Double-contrast fast spin echo imaging adds to the flexibility with which contrast can be varied (Figure 13). Asymmetric spin echo sequences¹³ can be used to highlight T_2^* effects (Figure 14).

A crossover occurs between the efficacy of two- and three-dimensional imaging¹⁴ so either is effective. Particularly effective are three-dimensional spin echo techniques, which provide fine anatomic detail (Figure 15).

6 SIGNAL-TO-NOISE RATIO AND FIELD STRENGTH

A perception exists that the signal-to-noise (S/N) ratio increases linearly with field strength. The physics of MRI shows that signal increases as the square of the field, and measurements and theoretical considerations (based on certain assumptions about the body) support a linear increase in noise with field, although the latter assumption should be considered

Figure 8 FSE imaging in a subject with multiple sclerosis. At high field, when a TR is long enough to make lesions bright, CSF is also very bright. Consequently, inversion recovery (IR) techniques are used to suppress CSF (FLAIR). The cost is in the inefficiency of IR imaging. FLAIR techniques can also be used at mid-field (a) ($TR=8$ s, $TE=120$ ms, $T_1=1.9$ s) but are not necessary, as shown in (b) ($TR=2000$ ms, $TE=60$ ms). Both images were obtained at 0.35 T. The mid-field image (a) requires $TR=267$ ms per slice, while without the IR pulse (b) TR is 91 ms

with caution. Based on these two factors, the ‘intrinsic’ S/N ratio should increase linearly with field. This simplistic view depends on disregarding all the factors that are important in imaging, all of which result in a much smaller increase than presumed.

In addition to the ‘intrinsic’ factor, the S/N ratio depends on the imaging conditions. Of interest is the S/N ratio per unit time for fixed voxel dimensions and imaged volume, as well as constant number of slices. For a 90° flip angle the relative S/N ratio will be proportional to

$$\{\exp(-TE/T_2)[1 - \exp(-TR/T_1)]\} \sqrt{\text{window length}} \sqrt{\text{slices}} / \sqrt{TR} \quad (1)$$

for two-dimensional FT imaging. The reasons for the $\sqrt{\text{slices}}$ term is that if sequence A yields 10 slices and sequence B yields 20 slices with one excitation, then to cover the same volume sequence A has to be run twice, while sequence B in the same time could be run once with two excitations and a gain of $\sqrt{2}$ in the S/N ratio. Similarly, the $\sqrt{TR}$ term comes in because, if two sequences provide the same coverage for one excitation, then the sequence with the shorter TR can be run with more excitations and increase the S/N ratio accordingly. For three-dimensional FT there is an additional $\sqrt{\text{slices}}$ term. For a discussion of the relative merits of two- and three-dimensional FT imaging the reader is directed to the paper by Carl-

Figure 9 Knee imaging in a subject with a bone marrow tumor. (a) Single-shot image for water. (b) Single-shot image of fat.

Figure 10 Gradient echo images of the knee in a subject with a vascular necrosis. (a) Water and fat in phase ($TE=20$ ms at 0.35 T). (b) Water and fat out of phase ($TE=30$ ms)

son et al.¹⁵ Based on imaging considerations we can analyze how the S/N ratio will behave.

6.1 T_1

As field strength increases, so does T_1 .^{1,2} A longer T_1 means smaller signals. For discussion purposes, consider T_1 varying as the square root of field strength. For a short TR sequence the signal will decrease linearly with T_1 , or as the square root of the field. For a long TR sequence the signal will not change much, but for a fixed TR the contrast will be lower, or for fixed contrast TR will be longer (longer imaging time). In this case the equivalent loss in S/N ratio will be smaller, approximately as the fourth root of field strength. Thus, for longer TR values, T_1 effects result in a loss in signal that increases as the fourth root to the square root of the field.

6.2 T_2

There is clear evidence that T_2 drops with field strength.² Between 0.063 and 3 T the T_2 of brain drops from about 80 to 58 ms, for muscle from 37 to 30 ms, and for liver from 49 to 25 ms. For a TE of 30 ms, this results in signal drops from

16% to 50%, corresponding to a 1/20 to 1/6 power of field for the loss in S/N ratio due to T_2 . The loss will be smaller for shorter TE and bigger for longer TE values.

6.3 Window Length

Chemical shift, susceptibility, and inhomogeneity limit window lengths. As discussed above, the artifacts depend linearly on field strength and window length. A shorter window reduces the artifacts, but also decreases the S/N ratio as the square root of window length. The net effect is that at a constant artifactual level there is a square root of field strength term available in the S/N ratio, favoring low field operation. In some sequences

Figure 11 Three-dimensional time-of-flight MRA at 0.35 T, acquisition time of 13.5 min

Figure 12 Sagittal C-spine images obtained with gradient echo imaging ($TR=360$ ms, $TE=30$ ms, flip angle = 15°)

Figure 13 Double-contrast fast spin echo (FSE) imaging in a subject with multiple sclerosis, using half-Fourier techniques. ($TR=2$ s, $TE=20/120$ ms, with 24 slices in 6.75 min)

this term is not usable, (for instance where TE is very short), and in others it is not fully usable, but in general it provides relative advantages of factors of 2–3 in S/N ratio for low-field operation.

6.4 Radiofrequency Power

As discussed above, high-field systems compromise slice profile in the interest of savings in peak and average rf power. At mid- and low-fields these conditions are not important, and square profiles can be obtained.¹⁶ For a system where a gap of 50% is needed to avoid interslice cross-talk, the loss in the S/N

ratio for the slice itself may amount to 20%, and the gap can be considered as an unused potential source of 50% more signal.¹⁷ Thus, the full S/N ratio is not being achieved if the slice profile is poor. The loss in two-dimensional FT imaging is sequence dependent. For three-dimensional FT imaging there is no difference.

6.5 Artifact Reduction

As discussed above, artifact reduction schemes take time away from data collection, either by reducing the echo window length or the number of sections, or by lengthening TE , and

Figure 14 Asymmetric spin echo sequence ($TE=15$ ms). An MRI-compatible biopsy needle inserted in beef is imaged with 5 ms offset (a) and zero offset (b). By varying the offset, the visibility of the needle can be altered during an interventional procedure

Figure 15 High-resolution head imaging using three-dimensional FSE (3 mm thickness, 0.5 mm resolution, 32 slices in 9.5 min)

may result in penalties in the S/N ratio per unit time. This loss depends on the particular sequence and can be as small as zero where artifact reduction is not needed, and as big as 50% in some extreme cases such as presaturation in multislice imaging.

6.6 Net S/N Ratio Change

From the above considerations it can be seen that the S/N ratio changes with field in a complex manner, which depends on the clinical purpose of the sequence, the type of sequence used and tissue imaged, on coverage (including gaps) and on artifacts. For a sequence such as MRA, a major part of the 'theoretical' S/N ratio available from increasing field strength can be obtained. For other sequences the gain is small. An approximate rule is that in many situations the S/N ratio increases as the third to fourth root of field strength, so that for a 20-fold increase in field, the S/N ratio is doubled or tripled.

7 DISCUSSION

In the excitement of academic work, commercial competition, and a desire to share by publication, we tend to forget that MRI, outside a relatively few research institutions, is nothing more than a diagnostic tool. Its value is based on diagnostic accuracy and noninvasiveness. The lower the cost at which the service can be delivered, the more the people with need can have access to it. Very few studies have rigorously compared diagnostic efficacy at different field strengths. One study, commissioned by the Australian Government, was a

broad based evaluation of five units at 0.3, 1.0, and 1.5 T.¹⁸ Another study was limited to head imaging, comparing 0.064 and 1.5 T units,¹⁹ and a ROC study of MS and knee imaging was recently published.²⁰ The earliest such study compared field strengths of 0.5, 1 and 1.5 T.²¹ None of these studies showed a statistically significant difference in efficacy. At the end of the 1990s, approximately 50% of the market in the USA is for open (low- and mid-field) MRI systems.

Biographical Sketches

Leon Kaufman. *b* 1942. B.S., 1964, (engineering), Ph.D., 1967, (physics), University of California, Berkeley. University of California, San Francisco, 1970–present. Introduced to NMR in a junior modern physics class; started NMR imaging project at UCSF in 1975. Currently, Professor of Physics and Director, UCSF-RIL. Approx. 400 publications. Research interests include image formation and interpretation, and socioeconomic aspects of the technology.

David M. Kramer. *b* 1952. B.A., 1973, (chemistry), Ph.D., 1978, (chemistry), State University of New York at Stony Brook. Worked on development of instrumentation and methods for applications of NMR in medicine. Previously employed by Technicare, 1981–86. Currently, Associate Adjunct Professor of Physics at the University of California at San Francisco, Radiologic Imaging Laboratory and a development scientist for Toshiba America MRI.

Joseph W. Carlson. *b* 1957. A.B. 1979, (physics) Princeton University, Ph.D. 1985, (physics), University of California, Berkeley. Presently on faculty in radiology, University of California, San Francisco. Research interests are centered on the development of medical MRI technology, with emphasis on the physics of MRI, design and analysis of electromagnetic components of magnetic resonance imagers and data analysis.

Mitsuaki Arakawa. *b* 1943. B.S., 1966, (physics), Seoul University. Introduced to NMR at Japan Electron Optics Laboratory, 1970, and by Lawrence Crooks and Leon Kaufman. University of California, San Francisco, 1977–present. Approx. 60 publications, including a chapter in the book *NMR in Medicine—Its Basic and Clinical Application* (in Japanese). Holds 18 US patents. Research and engineering interests include MRI detectors, and their interface and general instrumentation.

Magnetic Resonance Imaging: A Historical Overview

E. Raymond Andrew

University of Florida, Gainesville, FL, USA

1 INTRODUCTION

MRI has become a most powerful modality of radiological imaging and is now found in all major hospitals throughout the world. It is a technique which provides the physician with clear pictures of the interior of the human body from any angle without using hazardous radiations. In the future it promises to provide interventional images to guide operations in progress. It is already giving valuable insights into the detailed functioning of the brain. Physicians sometimes express surprise that the basic phenomenon on which MRI is based was discovered 50 years ago. In this historical overview of MRI we therefore begin with a brief account of the origins of NMR and its applications in physics and chemistry and then go on to describe in more detail its applications in biology and medicine, with particular reference to MRI.^{1,2}

2 DISCOVERY

The first successful demonstrations of NMR in bulk matter were published in 1946. Two independent groups, unknown to each other, working in physics laboratories on opposite coasts of the USA, discovered NMR almost simultaneously. Bloch, Hansen, and Packard,³ working at Stanford University, and Purcell, Torrey, and Pound,⁴ working at Harvard University, published their results in consecutive issues of *Physical Review*. The impact of their work was immediate, and applications of NMR have widened steadily from physics and chemistry to a broad range of disciplines from archeology to medicine. The importance of the discovery was recognized by the joint award of the 1952 Nobel Prize for Physics to the two leaders, Bloch and Purcell. Professor Bloch died in 1983; Professor Purcell died in 1997.

These early experiments were described by their discoverers in quite different physical terms, and it was only after discussion between the two groups that it was realized that their discoveries were essentially identical. At Harvard University the emphasis was on transitions of magnetic nuclei between quantized states in a magnetic field and on resonant absorption of radiofrequency energy. At Stanford University the description was of the precession of nuclear magnetization in a magnetic field, inducing an electromotive force (EMF) in the surrounding radiofrequency coil. The first description led to the

name 'nuclear magnetic resonance' for the phenomenon, and the second to the name 'nuclear induction'. These two descriptions, which can be shown to be quantitatively equivalent,⁵ still provide complementary views of the basic phenomenon, which are mutually illuminating. Today everyone uses the name 'nuclear magnetic resonance', but the alternative 'nuclear induction' is still often used by physicists and particularly survives in the term 'free induction decay' (FID) for the NMR signal following an exciting pulse.

Although NMR was first discovered and experimentally demonstrated in ordinary materials in 1945, the subject did have a prehistory. In 1936 Gorter⁶ looked for the resonance of ⁷Li nuclei in crystalline lithium fluoride and of protons in crystalline potassium alum, but without success. The failure of these early experiments and of some later attempts⁷ was attributed to the use of unfavorable materials.⁸ Meantime, NMR was first demonstrated in molecular beams by Rabi and co-workers⁹ at Columbia University in the USA in 1939. Although the fundamental principles are closely similar, applications of NMR to atomic and molecular beams represent a separate subject from NMR in ordinary materials with which we are concerned here.

Now that hospitals are spending vast sums on NMR clinical equipment it is sobering to recall that the first NMR experiments were done at almost no cost at all. The Harvard University group borrowed a large electromagnet previously used in cosmic ray experiments, which in turn had been converted from a discarded generator from the Boston elevated railway. At Stanford University an electromagnet was borrowed from the physics lecture theater, and only a few hundred dollars were spent, mainly on an oscilloscope.

3 PHYSICS

Many physicists joined this exciting new field of research over the next few years, and NMR was detected for almost all magnetic nuclei in the Periodic Table. NMR was detected in solids, liquids, and gases, in insulators, semiconductors, and metals, in polymers, membranes, and adsorbed and occluded phases, indeed in matter in all its forms. Resonances in liquids and gases were remarkably sharp, those from solids somewhat broader. Exploiting the sharpness of the resonances from fluids, extremely precise measurements were made of nuclear magnetic moments; nuclear spins were determined or confirmed and other nuclear parameters obtained.

Since the NMR frequency is directly proportional to the magnetic field strength, NMR presented the physicist with an excellent magnetometer for measurement of unknown magnetic fields in the laboratory. The method was readily extended to the Earth's magnetic field, and became useful in civil engineering projects, in archeological surveys for buried magnetic materials, for aerial geomagnetic surveys, for oceanographic surveys, and for measurements in space. The high precision of magnetic field measurement enabled more precise measurements to be made of some of the fundamental constants of physics.⁵

From the very beginning, the importance of relaxation times in NMR had been realized. At Stanford University the proton NMR was first found in water, and a paramagnetic salt was dissolved in the water in some experiments with a view to shortening the relaxation time.³ At Harvard University the pro-

ton NMR was first found in solid paraffin,⁴ and great pains were taken to use an extremely low radiofrequency power level to avoid saturation. The relaxation times T_1 and T_2 were introduced at the outset, and the foundations for understanding these basic quantities were laid in famous pioneering papers by Bloch,^{10,11} Purcell,¹² and their colleagues; to all NMR practitioners interested in relaxation processes this last paper¹² is known simply as 'BPP' (Bloembergen, Purcell, and Pound). Fundamental studies of relaxation behavior in solids and liquids have given great insight into molecular dynamics in a wide range of materials, including cellular systems and living tissues.

In the early years NMR was detected using a steady source of resonant radiofrequency radiation, often referred to as continuous wave (CW) detection. The spectacular discovery of spin echoes by Hahn¹³ stimulated the widespread use of pulsed NMR. The NMR spectrum could be obtained by Fourier transformation of the free induction decay with tremendous savings of time, and relaxation times could be determined with greater simplicity.

In the first decade of its activity, NMR was largely the province of the physicist and the physical chemist. By 1954 some 400 papers had been published, and the first book on NMR⁵ was able to make reference to all of them. Two later books^{14,15} devoted to the fundamental physical principles of NMR have become landmarks in the development of the subject.

4 CHEMISTRY

Quite early it had been noted by several workers¹⁶⁻¹⁸ that the NMR frequency of a given nucleus was to a small degree dependent on the chemical form in which the element was present. The molecular electrons slightly shielded the nucleus and shifted the resonance; the effect was appropriately called the chemical shift. Consequently, a molecule with nuclei in several environments generated a spectrum with several distinct NMR responses, and the subject of NMR spectroscopy had begun.¹⁹ Spin multiplets provided finer features in the NMR spectrum.^{20,21} The NMR spectrum was thus a fingerprint of the chemical compound and enabled NMR spectroscopy to become one of the chemist's most valuable structural and analytical tools.

The NMR spectral lines are narrow and close together; consequently the development of high-resolution NMR spectroscopy called for very uniform magnetic fields, uniform to 1 part in 10^8 or better over a 1 mL sample. Varian Associates in California can be credited fairly with opening up this field to chemists generally in the late 1950s by responding to the challenge posed by small proton chemical shift differences and providing NMR spectrometers with magnets having the requisite uniformity of field. In the quest for improved resolution and sensitivity the proton NMR frequency was steadily advanced from 30 to 60 to 100 MHz, this last frequency corresponding to a magnetic field of 2.3 T. Many other nuclei, especially ^{13}C , ^{19}F , and ^{31}P , were exploited under high-resolution conditions. Pulse methods replaced CW, and a dedicated computer became an integral part of the spectrometer system, controlling the pulse sequences, gathering the data, performing the Fourier transforms, and displaying the spectra.

The pursuit of still higher resolution and sensitivity called for still higher magnetic fields, which in turn required a change of magnet technology from the iron electromagnets used hitherto. Using superconducting magnets, proton NMR spectra are now recorded at frequencies up to 1 GHz in fields up to 20 T. Designs are in hand at the US National High Magnetic Field Laboratory in Florida for high-resolution proton NMR spectroscopy at 900 MHz and eventually at 1 GHz, which will require a high-resolution superconducting magnet with a field of 23.5 T.

The investigation of larger molecules including peptides, proteins, enzymes, and nucleic acids yielded spectra with a forest of fine lines difficult to resolve and assign. The advent of 2D NMR spectroscopy,²² spreading out the spectra in two dimensions with detailed connectivity, gave great spectral clarity and renewed impetus. This has been extended to three dimensions and beyond.

Nowadays no chemistry research laboratory is properly equipped without its high-resolution NMR spectrometer. The widespread use of NMR spectrometers in chemical laboratories has led to the growth of a substantial NMR instrument industry. The principles and practice of NMR are now a feature of chemistry courses at quite elementary levels. Most science students and medical students today will have heard of NMR before going to university. The use of high-resolution NMR spectroscopy has spread from chemistry to biochemistry, microbiology, pharmacy, agricultural chemistry, polymer science, and, as we shall see, biology and medicine.

We note in passing that specimens investigated by chemists and physicists are usually homogeneous and rather less than 1 ml in volume. Consequently, the bore of a superconducting NMR magnet for such work is usually about 5 cm in diameter. This provides just sufficient access for the specimen, its surrounding radiofrequency probe, and other accessories.

5 BIOLOGY

The earliest biological NMR experiments take us back to the inventors of the subject. Soon after the first successful NMR experiments at Stanford University,³ Bloch obtained a strong proton NMR signal when he inserted his finger in the radiofrequency coil of his spectrometer. In 1948, Purcell and Ramsey in turn inserted their heads into the 2 T field of the Harvard University cyclotron; around their heads was a coil connected to a powerful radiofrequency generator tuned to the proton NMR frequency. The only sensation recorded was that of EMFs generated in the metal fillings of their teeth as their heads were moved into and out of the magnet and detected by their tongues. Fifty years later there is no evidence of any damage arising from this magnetic adventure.

Occasional NMR experiments were subsequently reported on materials of biological interest.^{23,24} A pioneering series of investigations was carried out by Odeblad and his colleagues in Stockholm on tissues and fluids from animals and humans starting in 1955 and continuing over the next decade. These studies included blood cells,^{25,26} cervical mucus,²⁷ tissues and fluids of the eye²⁸ and the eye lens,²⁹ saliva,³⁰ and muscle.³¹ However, substantial advances in the application of NMR in biology awaited the development of high-field, high-resolution, Fourier transform spectrometers in the late 1960s. As men-

tioned in the previous section, these technical advances enabled high-resolution NMR spectra in one and two dimensions to be obtained, and yielded structural and dynamic information of importance in biochemistry and molecular biology.

At the same time, high-resolution NMR spectroscopy began to be applied to living systems. First Moon and Richards³² reported high-resolution ^{31}P NMR studies of intact red blood cells in which they could assign lines to individual metabolites. This was followed the next year by recordings of ^{31}P spectra from an intact freshly excised muscle from the leg of a rat by Hoult et al.³³ It was found possible to maintain muscles in good physiological condition in the spectrometer and to record the effects of electrical stimulation. The 5 cm diameter bore of a conventional NMR superconducting magnet was nevertheless a severe restriction. Soon magnets with a 10 cm diameter bore were provided, and a wide range of studies on perfused animal hearts, kidneys, livers, and other organs were pursued, using mainly ^{31}P NMR but also ^1H and ^{13}C NMR spectroscopy.

It was then a natural step to examine whole intact living organisms from bacteria to mice, rats, and rabbits. With animals it was of course important to know from what anatomical part or organ the NMR spectrum originates. In some cases this could be achieved by winding the radiofrequency coil around the part concerned; in other cases a radiofrequency coil was placed on the surface of the animal to record the NMR signal from the region immediately below.

From animals it was just a further step to the *in vivo* NMR spectroscopy of humans and its applications in medicine. Spatial localization continued to be an important challenge, and other more sophisticated methods were introduced such as ISIS and spectroscopic imaging. However, in this article we shall not follow this trail further. Instead we follow the parallel trail of MRI in the next section. Further information on magnetic

resonance spectroscopy (MRS) may be found in books by Gadian,³⁴ Andrew et al.,³⁵ Gillies³⁶ and in other articles in these volumes.

6 MAGNETIC RESONANCE IMAGING

In contrast to the steady onward march of NMR spectroscopy from physics through chemistry and biology to medicine, NMR imaging represents a distinctly different approach which appeared rather suddenly on the scene in 1973.

In 1973, Lauterbur³⁷ published the first NMR 2D image of a heterogeneous structured object: two tubes of water. He pointed out the simple fact that if a field gradient is applied to a structured object each nucleus responds with its own NMR frequency determined by its position; the NMR spectrum is the 1D projection of nuclear density along the gradient direction. Applying the gradient in a series of directions and so obtaining a series of projections, he devised an algorithm to generate a 2D proton NMR image of the object from its projections, in just the same way as it is done in X ray computed tomography (CT) scanning. This first image is reproduced in Figure 1.

The impact of this first image and of the work that followed has been tremendous. Within a decade of its publication, manufacturers worldwide were producing NMR scanners that generated high quality images of all parts of the human body, challenging traditional modalities of radiological imaging in clinical practice. After two decades all major hospitals are now equipped with NMR whole body scanners—over 10000 systems worldwide—and the total expenditure for this equipment overshadows that for all previous uses of NMR. Moreover, it

Figure 1 The first 2D NMR image (Lauterbur³⁷)

has brought NMR to the notice of the man and woman in the street, and NMR has entered our everyday vocabulary. In the interests of simplicity and the happiness of patients the adjective ‘nuclear’ has been dropped in the context of medicine, and the subject is now just ‘magnetic resonance imaging’ or MRI. Other names, such as Zeugmatography, introduced by Lauterbur,³⁷ have now largely dropped out of use.

Just as in NMR itself there was a prehistory before the final discovery (see above), so in NMR imaging there was a prehistory in the use of magnetic field gradients. NMR 1D projections in a magnetic field gradient were investigated quite early in 1951–52 with simple glass and liquid structures by Gabillard^{38–40} in France. The dynamic NMR response is given by the Fourier transform of the distribution function of nuclei in the gradient applied to the structure, and it follows conversely that a 1D projection is obtained from the Fourier transform of the free induction decay.

Magnetic field gradients are a basic feature in the study of molecular diffusion in liquids by the NMR spin echo method. The diffusion of molecules from their original locations in a liquid sample in a field gradient reduces their contribution to the echo, and this enables the diffusion constant of the liquid to be determined.^{13,41}

In 1956, Walters and Fairbank⁴² studied the distribution of ^3He in liquid ^3He – ^4He solutions in three vertically arranged connected containers by applying a field gradient from top to bottom. A separate ^3He NMR signal was recorded from each container. In this way phase separations below 0.8 K were determined. In this experiment the field gradient was being used to provide a 1D NMR image of the ^3He density in the containers.

Magnetic field gradients are a feature of NMR methods of information storage.^{43,44} In one method,⁴⁴ information is stored in a 3D cellular structure and refreshed frequently to avoid loss by relaxation. The information is then retrieved by application of gradients which enable the specific location of the desired piece of information in the store to be excited. Reading the information from such an information store was in fact an early NMR imaging procedure, which could be used in one, two, or three dimensions.

In 1972, Damadian^{45,46} filed a prophetic patent in which he proposed without detail a method for scanning the human body (Figure 2) by NMR and detecting pathological deviations, for example cancer, through differences in the relaxation times T_1 and T_2 . This proposal was based on his pioneering observations⁴⁷ that the relaxation times T_1 and T_2 were significantly higher in cancerous rat tissue than in the corresponding normal tissue.

In 1973, Mansfield and Grannell⁴⁸ introduced the concept of NMR diffraction in solids. Multiple pulse line narrowing sequences sharpened the NMR response, and a magnetic field gradient provided spatial resolution. A model 1D lattice of several plates of camphor was used to generate the 1D images shown in Figure 3. While technical difficulties might prevent application to crystallographic structures, it was suggested that the method would be useful in the study of biophysical systems with regular or approximately regular macroscopic structures such as cell membranes and filamentary or fibrous structures. In 1975 in an amplification and extension of this work⁴⁹ the authors discuss the application of these ideas to more general nonperiodic structures, including microstructures.

Figure 2 An early schematic diagram for human NMR imaging (Damadian^{45,46})

A magnetic resonance image is a 2D representation of the NMR signal from the resonant nuclei in a particular thin slice of the object of interest. We may imagine the slice divided up into an array of $n \times n$ elements. If we are able to measure the NMR signal from all n^2 elements in the slice, we can construct a picture or image consisting of these $n \times n$ picture elements (pixels). The larger the value of n , the finer is the detail in the

Figure 3 1D NMR images of (a) one, (b) three, and (c) five layers of camphor (Mansfield and Grannell⁴⁸)

Figure 4 A classification of imaging methods³⁵

image. However, if we were to double the value of n in order to improve the resolution, we should have to measure four times as many pixels, each containing only a quarter the number of nuclei from which to generate their NMR signals. In practice, n is usually 256 or 512; computers are happy with numbers that are powers of 2.

A field gradient is an essentially 1D probe, and many different methods have been advanced for manipulating the gradient to secure 2D or 3D information. A basic classification of methods is illustrated in Figure 4. First we might arrange to isolate a small volume and collect the NMR signals from it. This elemental volume may then be traversed through a plane in the object of interest, enabling us to build a magnetic resonance image of a plane, point by point. This is the sequential point method, and it is inevitably slow. Next we might arrange to gather the NMR signal from a whole line or column of n elements simultaneously by a Fourier transform procedure, which is n times faster. If n is 256, this represents a substantial gain. This is line scanning. We can then scan the line through the plane of interest to build an image.

Then we might gather the NMR signal from a whole plane of n^2 pixels simultaneously and process the data in such a way that we get an image of the plane. This is planar imaging. It may not necessarily be faster than line scanning, but since NMR signals are being gathered from the whole plane all the time it will certainly give a much better quality image. Finally, we might gather the NMR signal from the whole 3D object simultaneously and process the data in such a way as to characterize all $n \times n \times n = n^3$ volume elements (voxels). This is 3D imaging. An image of any desired slice can then be displayed.

The first two methods (sequential point and line scanning) were important in the early days of MRI,^{50–53} but have now been superseded by the third (planar imaging). 3D imaging is available on many instruments but takes longer and gives more information than is generally needed. Planar imaging may be achieved by the projection-reconstruction method³⁷ or more usually by the 2D Fourier imaging method devised by Kumar, Welte, and Ernst,⁵⁴ which is readily extensible to three dimensions. A careful assessment of the relative performance of the various imaging methods was carried out by Brunner and Ernst.⁵⁵

In order to do planar imaging it is of course necessary to define the slice to be imaged. This is usually achieved by the selective excitation method of Garroway, Grannell, and Mansfield.⁵⁶ Implementation of the 2D Fourier imaging method usually makes use of the spin warp technique developed by Edelstein, Hutchison, Johnson, and Redpath.⁵⁷

The first MRI experiments were carried out in physics and chemistry laboratories using modified NMR spectrometers with

magnets which had limited access. The imaging subjects were therefore necessarily small. Over the period 1974–78, NMR images were published from the fruit and vegetable kingdom: pecan,⁵⁸ onion,⁵¹ lemon^{59,60} (see Figure 5), pepper,⁶¹ and okra.⁶² Images were also published from the animal kingdom: clam,⁵⁸ chicken wing,⁵¹ turkey leg,⁶³ mouse,^{58,64–66} rat,^{67–69} and rabbit⁷⁰ (see Figure 6). These pictures showed that geometrically faithful NMR images could be obtained of the interior of biological structures, with contrast arising from differences in tissue density, mobility and relaxation. The stage was set for applications of MRI to the human body.

Figure 5 (a) Thin transverse section proton NMR image of an intact lemon and (b) a photograph of the actual section cut subsequently (Andrew et al.⁵⁹ and Andrew⁶⁰)

Figure 6 Thin coronal section proton NMR image through the orbits of the head of a rabbit (Hinshaw et al.⁷⁰)

7 HUMAN MRI

The first human NMR image, reported in 1976 by Mansfield and Maudsley,^{71,72} was of a live human finger (Figure 7). The finger could be inserted into the 5 cm gap of a conventional iron NMR electromagnet. Using a magnet with a 12 cm gap, NMR images were obtained of a live human hand,⁶⁷ wrist^{73,74} (Figure 8), and forearm⁷⁵ by Hinshaw, Andrew, Bottomley, and their co-workers. The anatomical detail and tissue contrast

Figure 7 Cross-section proton NMR image of a live human finger (Mansfield and Maudsley^{71,72})

Figure 8 Thin proton NMR image of a live human wrist (bottom). For comparison, a cross section of an actual wrist is also shown (top) (Hinshaw et al.^{73,74})

Figure 9 Whole body NMR imaging magnet at Nottingham University, 1978

Figure 11 The first superconducting whole body magnet for regular clinical use, installed at Hammersmith Hospital, London, 1981

were good and gave optimism for successful NMR imaging of the whole human body, head, chest, and abdomen.

An essential requirement of human MRI was a magnet capable of accepting the whole human body and generating a magnetic field uniform and stable to at least 1 part in 10^5 over a central sphere about 30 cm in diameter. Early whole body magnets were air cored resistive solenoids producing fields up to 0.15 T, with an aperture of about 80 cm in diameter. An

Figure 12 Transverse NMR image of a normal human thorax (Damadian et al.^{52,77})

Figure 13 Transverse NMR image of a normal human abdomen (Mansfield et al.⁷⁹)

example used in the University of Nottingham in 1978 is shown in Figure 9; a commercial version in clinical use in 1983 in the University of Florida is shown in Figure 10. A similar magnet but with a vertical axis was used in Aberdeen.⁶⁶ For higher field strengths superconducting solenoids are generally used, although at least one system uses a large permanent magnet and another uses an iron electromagnet. The development of high-field whole body superconducting magnets has played a crucial role in opening up clinical MRI; Oxford Instruments in the UK in particular were pioneers in this development. The first superconducting whole body magnet for clinical use was installed at Hammersmith Hospital, London in 1981 (Figure 11).

Biological tissues are moderate electrical conductors, and we might therefore expect some attenuation of the electromagnetic radiation at the NMR frequency as it penetrates the body. Calculations by Bottomley and Andrew⁷⁶ suggested that significant attenuation and phase distortion might be encountered above 40 MHz, corresponding to 1 T for proton NMR. Actually the calculations were based on a homogeneous cylinder 20 cm in radius, which was somewhat pessimistic since the human body contains many cavities. In practice little attenuation is seen at 2 T (85 MHz for protons), but has been noticed at 4 T.

The first human whole body MR image was an image of the human thorax by Damadian, Goldsmith, and Minkoff^{52,77} in 1977 (Figure 12). This was closely followed in 1978 by the first magnetic resonance image of the human head, by Clow and Young,⁷⁸ and the first image of the human abdomen, by Mansfield, Pykett, Morris, and Coupland⁷⁹ (Figure 13). In computerized X-ray tomography the slice imaged was usually transverse. Such a restriction does not apply in MRI, and this was clearly demonstrated with the publication in 1980 of the first coronal and sagittal images of the human head by Holland, Hawkes, and Moore⁸⁰ (Figure 14).

These early human images were all of normal healthy volunteers. Soon afterwards in 1980 the first images of human pathology began to appear. Hawkes, Holland, Moore, and Worthington⁸¹ demonstrated a wide range of intracranial pathological behavior by MRI. This included examples of

Figure 14 Transverse and first coronal and sagittal NMR images of a normal human head (Holland et al.⁸⁰)

hydrocephalus, a variety of tumors, aneurysms, arteriovenous malformations, and chronic sinus infection. Damadian⁴⁶ demonstrated a number of cases of carcinoma of the chest.

We should notice that when imaging the human body, the proton is by far the most commonly used nucleus. After all, hydrogen is the most abundant chemical element in the body, ^1H is isotopically almost 100% abundant, and it has the highest magnetic moment among stable nuclei. The next most abundant chemical element, oxygen, has no convenient magnetic isotope. For carbon, the isotope ^{13}C is only 1.1% abundant and it has a low magnetic moment. The principal isotope of nitrogen is ^{14}N , which has a low magnetic moment and other complications, while ^{15}N has a low abundance. Phosphorus is an element of considerable interest on account of the important metabolites that contain it. The isotope ^{31}P is 100% abundant and it has a reasonable magnetic moment. However, concentrations of phosphorus are very low in living systems. So summarizing, protons (hydrogen nuclei) are by far the best nuclei for human MRI. Nevertheless there has been some MRI interest in ^2D , ^7Li , ^{14}N , ^{19}F , ^{23}Na , and ^{31}P . Some early work has also been done on MRI of unpaired electrons.⁸²

Since the first successful human magnetic resonance images of healthy volunteers and patients there has been a rapid devel-

opment of technique and a great improvement in the quality of the images. By 1983 the first commercial MRI systems were being installed in hospitals, yielding images in 4 min with 1 mm resolution. No longer do physicists and chemists and others make their own MRI systems. Images of the author taken in March 1984 using the 0.15 T magnet of Figure 10 are shown in Figure 15, illustrating the performance reached at that time. With the availability of higher fields to 2 T images have improved steadily since then. Magnets with fields of 3, 4, and 5 T have been built for human imaging but are not yet in general use.

Over the past decade, MRI has become an accepted modality of clinical radiology. We may note some of the advantages which recommend it. First it does not use ionizing radiation and is intrinsically safer than modalities using X-rays, γ rays, positrons, or heavy ions. In contrast with ultrasound the radiation penetrates bony structures. Besides giving morphological information, MRI gives additional diagnostic insights and improved contrast through relaxation parameters, susceptibility, and diffusion, not available from other modalities. In contrast with CT, MRI provides direct images in transverse, coronal, or sagittal slices, or slices of arbitrary orientation. Flow can be measured. Contrast may be improved by injection of paramagnetic agents.

Conventional magnetic resonance images take several minutes to acquire whereas CT images take several seconds only. However, it is possible to acquire simultaneously magnetic resonance images from typically 10 parallel slices and four T_2 -weighted images of each, a total of 40 images in the time of one, making an average acquisition time of only a few seconds. Further, using new techniques such as FLASH⁸³ a single magnetic resonance image can be acquired in a few seconds. Still faster magnetic resonance images may be obtained using a sequence proposed by Mansfield⁸⁴ back in 1977, and demonstrated the following year,⁶² called echo planar imaging. A complete image could be obtained in less than 0.1 s, enabling real time movie magnetic resonance images to be recorded.⁸⁵

8 CONCLUDING REMARKS

The rapid expansion of interest in NMR of living systems led to the organization of special conferences to discuss these topics. In March 1979 the Royal Society held a Discussion Meeting in London entitled 'Nuclear magnetic resonance in intact biological systems', which reviewed achievements to date in both MRI and MRS. The papers given at this meeting were published as a special issue of *Philosophical Transactions of the Royal Society*, (1980, Vol. 289, no. 1037), and constitute a historic landmark in the development of the subject. In October 1981 another significant meeting devoted solely to MRI was held in Winston-Salem, North Carolina. With the widespread deployment of commercial MRI systems in all major hospitals it was clear that annual meetings were needed, and the Society of Magnetic Resonance in Medicine was formed, holding its first meeting in Boston, Massachusetts, in August 1982 with an attendance of 800 participants. Since then the Society has met annually in August either in North America or in Europe; by 1993 attendance had trebled. In 1983 the Society started a new journal *Magnetic Resonance in Medicine*, edited by E. Ray-

Figure 15 Magnetic resonance images of the author taken in March 1984, using the magnet of Figure 8: (a) head, transverse; (b) head, sagittal; (c) spine, sagittal; (d) abdomen, transverse

mond Andrew, and since 1991 by Felix Wehrli. Other societies and journals began at this time in various parts of the world.

This historical overview covers the period up to 1983. The reader can now go on to embrace the multitude of detailed applications of MRI to every branch and corner of medicine, to microimaging, spectroscopic imaging, functional brain imaging, interventional MRI, to the solid state, and much more. Many of these developments are covered in recent books such as that by Morris⁸⁶ for the mathematically inclined reader or that by Andrew et al.,³⁵ which is addressed particularly to physicians; it has no mathematics and covers both MRI and MRS. More detailed information on very many topics relating to MRI will found elsewhere in these volumes.

MRI at Midfield Strength

Jane M. Hawnaur and Ian Isherwood

Department of Diagnostic Radiology, University of Manchester, UK

1 INTRODUCTION

Whole body magnetic resonance imaging (MRI) was initially performed in the early 1980s using magnetic resonance (MR) scanners based on resistive electromagnets. In the decade that followed, superconducting MR scanners became the most popular scanners for both research and clinical purposes. The superior signal-to-noise ratio (S/N), field homogeneity and field stability, particularly for high field (1.5 T) systems, proved to be major factors in this selective process. An initial emphasis on brain and spine imaging during the early development of MRI served to reinforce the concept that a high field strength was necessary for good quality images, a view encouraged by some of the systems manufacturers.

Since then, manufacturers have expended significant research and development effort on their midfield range of systems, many of which now offer the same capabilities (apart from spectroscopy) as higher field MRI systems. As diagnostic applications for MRI have expanded outside the central nervous system into the musculoskeletal and cardiovascular systems, abdomen, and pelvis, some of the disadvantages of high-field MRI have become more apparent. Chemical shift, susceptibility effects and movement artifacts cause greater interference during body imaging than cranial or spinal imaging. In addition, the practical and economic difficulties associated with the installation and running of high-field systems in some hospital settings have prompted reassessment of the value of low and midfield systems as a necessary compromise between S/N, versatility and cost. Of 719 MRI systems installed in Japan by 1990, 72 were low-field (less than 0.2 T), 488 were midfield (0.2–1.0 T), and 159 were 1.5 T superconducting systems.¹ A similar trend away from high-field systems was apparent worldwide; sales of midfield MRI scanners worldwide exceed sales of high-field systems by a factor of 2–3, and the single most popular model in Europe is a 1.0 T superconducting MR scanner.

2 TYPES OF SCANNER AT MIDFIELD (0.2–1.0 T)

Most of the components of MRI scanners for use at mid and high field are identical apart from the magnet itself. There are three types of magnet design capable of operating in the midfield range.

2.1 Superconducting Magnets

2.1.1 Design

MRI scanners using a superconducting magnet offer a wide range of field strengths from 0.2 T upwards and are the most

popular choice for clinical whole body systems operating at 0.5 or 1.0 T. The field-generating coil is constructed from a superconducting alloy of niobium/titanium (NbTi) filaments in a copper matrix through which an electric current is passed. To remove electrical resistance, the system is cooled to 4 K. Once the superconducting state has been achieved, minimal electrical energy is required to maintain the magnetic field. The conducting NbTi wires are suspended in liquid helium, which evaporates as it absorbs heat conducted away from the wires. In older systems, the cooling system required several layers of vacuum insulation, liquid nitrogen and insulating materials around the helium cryostat, and was relatively inefficient. The helium boil-off rate was of the order of 1 L h⁻¹ and the inconvenience and cost of weekly or monthly cryogen refills was a major disadvantage of superconducting systems. In modern midfield scanners, however, efficient refrigeration is achieved without liquid nitrogen, and systems are designed to minimize cryogen costs. Helium boil-off rates vary between manufacturers, but are of the order of 0.04–0.2 L h⁻¹. Refill rates have consequently fallen, with recently introduced models offering refill intervals of up to 7 years.

2.1.2 Field Homogeneity and Shielding

Superconducting magnets produce a stable and homogeneous magnetic field; their solenoidal design produces a main magnetic field B_0 oriented along the length of the patient. Homogeneity is of the order of ± 2 –5 ppm on a 40 cm diameter spherical volume (DSV). Early designs reduced the fringe field passively by means of bolt-on steel shielding around the magnet, resulting in a combined weight of up to 40 ton. Active shielding, with an integral shielding coil built around the primary coil, is more efficient and less costly, reducing the weight of the scanner to around 5 ton for a 1.0 T magnet. Actively shielded magnets are thus more compact and lightweight, but there is a small reduction in magnetic field homogeneity and less protection from variation in external rf fields. Typical 5 G contours for a 0.5 T passively shielded superconducting MR system are 3.7 m axial by 2.5 m radial. Many manufacturers offer compact midfield systems with integral passive shielding, also resulting in a small fringe field.

2.1.3 Specifications

Many midfield superconducting magnets have been adapted from high-field systems in the same manufacturer's range, and offer similar facilities (Table 1).

2.1.4 Installation and Running Costs

A superconducting MR scanner in the midfield range weighs about 5 ton, including the enclosure, helium and gradient coils. This compares with a weight of 5–15 ton for a similar system operating at 1.5 T. Most current midfield MR scanners are designed for installation in an existing room within the imaging department. Minimum space requirements are typically 6.0 m × 5.0 m with a 2.65 m ceiling height. Additional space is required for computers and console area, generally less than 10 m² each. The capital cost of superconducting MR equipment is relatively high and installation may involve the expense of fringe field shielding, rf shielding, and ventilation to enable effective operation of the system.

Table 1 Selected Specifications for MR Systems from the Same Manufacturer Operating at 0.5 T and 1.5 T (Phillips) 1998

	0.5 T	1.5 T
Magnet homogeneity	± 1 ppm (40 cm DSV)	± 1 ppm (40 cm DSV)
Weight (similar dimensions) (kg)	2600	3100
Fringe field (5 G)	$2.9 \text{ m} \times 2.1 \text{ m}$	$3.9 \text{ m} \times 2.5 \text{ m}$
Helium consumption (L h^{-1})	0.004	0.004
Gradient:		
Strength (mT m^{-1})	15	15 (standard), 23 (upgrade)
Slew rate (mT ms^{-1})	17	17 (standard), 53 or 105 (upgrade)
Capabilities		
Spectroscopy	No	Yes
Diffusion imaging	Yes	Yes
Functional brain MRI	No	Yes
Angiography	Yes	Yes
Receiver coils		
Surface coils	Yes	Yes
Flexible torso surface coil	Yes	No
Multiple phased-array torso coil	No	Yes
Endoluminal coil	Yes	Yes
Siting:		
Magnet room	$6 \text{ m} \times 5 \text{ m}$	$6 \text{ m} \times 5 \text{ m}$
Technical room	$2 \text{ m} \times 3.2 \text{ m}$	$2 \text{ m} \times 3.2 \text{ m}$

DSV, diameter spherical volume

2.2 Resistive Magnets

2.2.1 Design

The static field from a resistive magnet is produced by electric current passing through coils or sheets of resistive wire wound around a central iron core. For example, a resistive magnet with a bore of about 1 m and a field strength of 0.15 T requires approximately 1500 turns of wire through which around 200 A of current is passed.

Resistive magnets usually have a solenoidal configuration with B_0 oriented along the long axis of the patient, but their relatively light weight enables them to be built with a vertical configuration which facilitates the use of rf receiver coils to generate a field perpendicular to B_0 . This design also increases access to the magnet bore for claustrophobic patients, interventional procedures, or for supervision of high-dependency patients. Magnetic field strength is limited by power consumption, the amount of heat produced, and the weight of magnet required to support a large number of turns of wire. Power is dissipated in the coil windings as heat is removed by air/water cooling, necessitating the delivery of large volumes of de-ionized water. A stable, continuous supply of electricity is required, and power consumption is high compared with permanent or superconducting magnets. A typical power requirement for a resistive magnet is of the order of 50 kW for a 0.15 T field, the power requirement increasing with increasing field strength. The fields of commercially available resistive MR systems range from 0.02 to 0.4 T. Air cored designs are also available.

2.2.2 Field Homogeneity and Shielding

A typical main field homogeneity in a shimmed resistive magnet over a 40 cm FOV is 20–200 ppm, i.e. less than for most superconducting magnets. Any problems in maintaining a

constant power supply can result in temporal instability of the magnetic field. Stability will also be affected by temperature variations if cooling and heat exchange systems malfunction. However, the magnetic field can be switched off easily to allow removal of metallic objects attached to the bore of the magnet.

2.2.3 Specifications

The weight and installation requirements for a 0.2 T resistive magnet are similar to those of 0.5 T superconducting scanners, and the imaging capabilities are broadly similar (Table 2).

2.2.4 Installation and Running Costs

Resistive MRI scanners are cheaper to buy than superconducting types, and cost less to install. Despite the relatively high electricity costs, running costs overall are less than those of superconducting magnets.

2.3 Permanent Magnets

2.3.1 Design

The magnetic field is generated by units of permanently magnetized material arranged to construct a magnet with north and south poles separated by an air gap of sufficient size for imaging. Permanent magnets usually have a horseshoe or bipolar shape, with the patient lying perpendicular to B_0 . Containment of the magnetic flux lines to produce a uniform field between the poles of the magnet requires a large mass of iron, with the result that a permanent MRI scanner is heavier than types using superconducting magnets. Modern systems weigh approximately 10 ton but lighter permanent magnets using rare earth alloys such as neodymium alloy are also available. MRI systems based on a permanent magnet have a limited field strength of up to 0.2–0.3 T. The extent of the

Table 2 Comparison of Representative Specifications of MR Systems available in mid-1990s

Field strength/type	Homogeneity	Installation area (m ²)	Fringe field, axial × vertical (m)	Weight (kg)
0.2 T Permanent	±20 ppm 1810 cm DSV	25	1.7 × 2.2	8900
0.2 T Resistive	±5 ppm 40 cm DSV	30	2.6 × 2.4	12 000
Superconducting: 0.5 T	±5 ppm 40 cm DSV	23	3.7 × 2.5, passive shield	7000
0.5 T	±5 ppm 40 cm DSV	25	3.5 × 2.5, active shield	2800
1.0 T	±7.5 ppm 50 cm DSV	40	2.4 × 4.3, active shield	4900
1.5 T	±5 ppm 50 cm DSV	65	3.1 × 5.0, active shield	13 100

DSV, diameter spherical volume

stray field is usually less than for wire-wound open-core magnets, but magnetic field intensity often rises sharply near the bore of the magnet and the ‘missile effect’ may be greater than for wire-wound magnets.² Systems are available with an open configuration, which reduces claustrophobia and improves access to high-dependency patients or for MR-guided interventional procedures. Solenoidal rf coils can be used to improve the S/N.

2.3.2 Field Homogeneity and Stability

Magnetic field homogeneity is of the order of 40 ppm on a 36 cm DSV, compared with 20 ppm on a 45 cm DSV for a 0.5 T actively shielded superconducting magnet. Variations in the temperature of the iron core will affect field strength, and field homogeneity can be ruined by damage to the magnet surface.

2.3.3 Specifications

The limited field strength is associated with an increase in examination time of 5–15% depending on the area being examined. A vertical field orientation is said to produce image quality similar to that of a 0.5 T system, and models are available with a three-dimensional imaging capability. Fast scan and MR angiography packages are available.

2.3.4 Installation and Running Costs

Permanent magnets are becoming more popular as alternatives to superconducting or resistive MR scanners in budget-conscious markets. Installation does not require magnetic shielding, a separate computer room, or special air conditioning. Running costs are about one-tenth of those for a superconducting magnet system, since permanent magnets use little electrical power and no cooling water or cryogens. The latter consideration is particularly important in Japan and Italy, where cryogens are expensive. Operational costs are also

reduced by a low downtime of around 5%. Installation requires a space of 25 m², similar to that for a computerized tomography (CT) scanner, and can be completed in 10 days.

3 ADVANTAGES OF MIDFIELD MRI

The specification of commercially available MRI scanners in the midfield range has improved in recent years, while the purchase price, installation, and running costs have fallen. Manufacturers have concentrated on reducing site costs whilst upgrading capabilities. Efficient refrigeration with low cryogen consumption helps to reduce running costs at midfield. Operating costs for midfield MR systems can be covered with an average daily patient volume of 6–7 patients, while up to 10 patients are required to cover costs on a high-field system, assuming similar reimbursement rates. The cost of a maintenance agreement for a representative 1.5 T MR scanner can be 30% greater than for a midfield system. The Guidelines published by the Medical Devices Directorate of the UK Department of Health (1993)² recommend that MR equipment is contained within a designated controlled area, encompassing the 5 G magnetic field contour. Selfshielded, lightweight magnets with tight fringe fields enable easy siting without major structural modification to existing rooms. The compact fringe field also enables magnetic-field-sensitive devices such as monitoring equipment to be taken into the magnet room, thus allowing MRI of high dependency patients. Compact fringe fields also help to limit staff exposure, which should not exceed 0.2 T to the whole body including the hands and limbs as an 8 h time-weighted-average exposure.

Intravascular devices exhibiting ferromagnetism display greater torque and magnetic susceptibility artifacts at 1.5 T than at 0.35 T.³

Acoustic noise levels in the magnet bore do not correlate as might be expected with magnetic field strength, averaging 82–93 dB on a range of MR instruments operating from 0.35 to

1.5 T.⁴ The level of noise depends more on the efficiency of damping of the gradient coil vibration in different manufacturers' systems and will always tend to be greater when using fast gradient recalled echo (GRE) sequences with short TR and TE times and thin sections. Ear protection should be worn when the level of acoustic noise exceeds 85 dB.

4 EFFECT OF FIELD STRENGTH ON IMAGING PARAMETERS AND OPTIONS

4.1 General Specifications

Advances in hardware and software first introduced for high-field systems are now available at midfield. Software packages for cardiac imaging and angiography, and software for reducing acquisition times are all available for midfield systems. The rf components of 0.5, 1.0, and 1.5 T systems available from the same manufacturer are in many cases identical, and 0.5 T systems are now available with 15 mT m^{-1} gradients. While systems with a wide variety of field strengths are capable of producing images of diagnostic quality, high-field systems can normally produce esthetically pleasing images more rapidly. The introduction of quadrature coils to midfield systems and the use of powerful computers to facilitate multiple system operations and improve patient throughput have reduced this differential. Endoluminal coils are becoming more available on midfield systems.

4.2 Signal-to-Noise Ratio

The S/N increases as the field strength. This advantage of high field strength MRI has to be weighed against the concomitant potential for greater image artifacts due to increased eddy currents, chemical shift, and susceptibility, as well as the potential risk of excessive rf power deposition or heating (see below). At any field strength, image quality is improved by using a surface receiver coil to improve the S/N.

4.3 Contrast

The ability to detect a structure on an MR image and differentiate it from neighboring tissues depends on spatial resolution and signal intensity differences. The latter can be partly manipulated by selection of appropriate pulse sequences but is largely determined by the T_1 and T_2 relaxation times of the tissues. The resonant frequency and T_1 relaxation time of protons increase with increasing magnetic field strength. T_1 values increase by approximately $400\text{--}500 \text{ ms T}^{-1}$, the values for normal and pathological tissue tending to converge and the T_1 -dependent contrast to decrease as field strength increases. T_2 contrast does not show the same degree of field dependence, most tissues having a T_2 value in the range $50\text{--}150 \text{ ms}$. Taking the effect of noise on image quality into consideration, however, there is a trend for the tissue contrast-to-noise ratio to increase with field up to 1.5 T.⁵

Tissue components exhibiting susceptibility effects, e.g. iron in liver or basal ganglia, may result in an overall reduction in T_2 relaxation time at higher field strength.

4.4 Fat Suppression

Chemical shift imaging depends on the difference in resonant frequency between water and fat hydrogen protons, which allows selective excitation of one or other species. The amount of chemical shift (3.3 ppm) is independent of field strength, but the difference in frequency is proportional to field strength. Separation of fat and water resonant frequencies is less pronounced at midfield (70 Hz at 0.5 T) than at high field (200 Hz at 1.5 T). Magnetic field homogeneity will also tend to be less at midfield than at high field, with the variation in resonant frequencies due to field inhomogeneity causing imperfect selective excitation. The effect of field inhomogeneity will be least when using small fields of view near the magnet center. When using a binomial pulse to achieve selective saturation, the interpulse spacing must be longer at lower field strengths to achieve the same chemical shift effect as at high field, thus limiting the minimum TE .⁶

The TE times at which fat and water protons are out of phase are inversely proportional to the field strength, i.e., are longer at midfield than at high field.

4.5 Magnetization Transfer Contrast

Magnetization transfer contrast (MTC) using saturation transfer techniques reflects cross relaxation between free water and water bound to macromolecules. The reduction of the net available magnetization and of T_1 in the 'free' pool by application of a saturating off-resonance rf pulse to the 'bound' protons is a field dependent phenomenon. Magnetization transfer rate decreases with increasing field strength, for example the magnetization transfer rate constant for white matter is 2.27 s^{-1} at 0.5 T and 1.42 s^{-1} at 1.5 T.⁷ Although the degree of MTC in a given tissue would be expected to diminish as the T_1 relaxation time shortens with decreasing field strength, satisfactory MTC images have been obtained at low and midfield strengths. Selective saturation is possible at midfield using off-resonance rf irradiation of short duration. Power deposition in the subject from the rf dose generated by the preirradiation pulse is also less of a limiting factor at midfield strength. The safety guidelines for exposure to rf energy in MRI currently recommend a limit of 1 W kg^{-1} body weight.⁸

4.6 Fast/High-Resolution Scanning

The ability to achieve sequences with short TR and TE times and low flip angles (fast scanning) and small field of view (FOV)/thin slice imaging (high-resolution) scanning is dependent on gradient strength and rise time rather than field strength. New systems of any field strength typically offer gradient strengths of $15\text{--}23 \text{ mT m}^{-1}$ and a rise time of less than 1 ms. Image contrast and S/N may be compromised in fast/high resolution sequences, and image quality is more difficult to maintain at midfield than high field, when the amount of tissue signal at midfield is intrinsically less.

4.7 Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) is not usually limited by S/N and does depend on contrast between flowing

blood and background tissues and adequate spatial resolution. Intravoxel phase dispersion, which is an important cause of loss of contrast in MRA, is reduced by minimizing field inhomogeneity and by using the minimum voxel size and shortest TE time possible. Systems with excellent magnetic field homogeneity, high gradient strengths and slew rates, and good S/N characteristics are required, these properties generally being associated with high-field MRI systems. However, satisfactory MR angiograms have been obtained on midfield superconducting MR scanners and on systems employing a permanent magnet with a field strength of 0.2 T.^{9,10} Permanent magnets suffer less from eddy current artifacts during gradient switching, thereby preserving field homogeneity and thus improving background suppression in MR angiograms. At low and midfield, T_1 relaxation times are relatively short, so that with time-of-flight (TOF) techniques based on flow-related enhancement, signal from flowing blood will tend to be greater at midfield than high field because of the reduction in saturation due to the more rapid T_1 recovery. Conversely, saturation of stationary tissue is more difficult for the same reason, so that relatively larger flip angles and shorter TE times have to be employed at midfield than at high field to achieve an adequate degree of background suppression. For example, at 0.5 T the flip angle used for two-dimensional TOF is typically 85°, whilst at 1.5 T a similar sequence would employ a flip angle of about 60°. The degree of artifactual loss of flow signal from local field inhomogeneities caused by metallic surgical clips adjacent to vessels is less at midfield than high field.

4.8 Echo Planar Imaging

Peripheral nerve stimulation has been experienced by volunteers undergoing echo planar imaging (EPI) on a 1.5 T MR system modified by the addition of high-performance gradient sets. Subjective twitches were felt when EPI was being performed near peak gradient operating levels of around 60 T s⁻¹.¹¹ US Food and Drug Administration guidelines recommend that the gradient operating levels are kept below 20 T s⁻¹ or one-third of the observed threshold for peripheral nerve stimulation. On 0.5 T EPI scanners (Mansfield, Nottingham), gradient operating levels are one-sixth of that inducing peripheral nerve stimulation. An inversion–recovery (IR) preparation pulse combined with EPI at 0.5 T produces T_1 -weighted images in which tissue contrast can be optimized, with potential applications in dynamic contrast-enhanced studies.¹² Gradient strengths and switching rates are very similar for snapshot FLASH techniques and EPI.

4.9 MR Spectroscopy

³¹P MR spectroscopy (MRS) requires a minimum field strength of 1.5 T, but ¹H MR spectroscopy is feasible at lower field strengths. Stimulated echo acquisition mode ¹H MRS at 1.0 T demonstrates cerebral metabolites such as *N*-acetylaspartate and creatinine without significant loss of relative spectral resolution, compared with higher fields.¹³

5 ARTIFACTS

5.1 Motion

Ghost artifacts due to physiological motion during image acquisition occur in the phase-encoding direction and are most conspicuous when the moving tissue has a bright signal, e.g. fat in the abdominal wall or flowing blood on gradient echo sequences. Breathing artifacts are more apparent at high field strength than at low to midfield strength, due to the greater S/N (and fewer averages used) and higher fat–muscle contrast on the image.¹⁴

5.2 Chemical Shift

Chemical shift misregistration causes displacement of fat–water interfaces along the frequency-encoding direction due to the difference in the resonant frequencies of fat and water protons. This phenomenon is an important cause of error in the evaluation of tissue interfaces, particularly in areas containing abundant fat–soft tissue interfaces such as the orbit, extracranial head and neck, abdominal and pelvic cavities, and the musculoskeletal system. The amount of chemical shift increases with increasing field strength, despite the larger imaging gradients that are often integral to high-field systems.¹⁵ Many manufacturers of midfield systems offer the option of variable bandwidth, narrowing the bandwidth when an increase in S/N is desirable, or using a wider bandwidth to minimize chemical shift.

5.3 Susceptibility

The magnetic susceptibility of a material describes its ability to become magnetized in an external magnetic field. Susceptibility artifacts occur at the interface between materials having different susceptibilities and result in local field inhomogeneities and image distortion in the frequency-encoding direction. Artifactual image degradation is greater at high field than at mid or low field and when using GRE sequences rather than spin echo (SE) sequences, particularly T_2^* -weighted GRE sequences.

6 CLINICAL APPLICATIONS OF MIDFIELD VERSUS HIGH-FIELD MRI

6.1 Diagnostic Accuracy

Images obtained at both 0.5 and 1.5 T using similar protocols have been reviewed in a blind study of patients with various craniospinal, abdominal, and joint conditions. Receiver-operated characteristic (ROC) analysis of interpretation by expert radiologists at 0.5 and 1.5 T suggested that the differences in field strength are not significant for diagnostic accuracy.¹⁶ The S/N increases linearly with field strength, conferring an advantage on high-field systems, particularly when imaging small structures using a high-resolution matrix and thin slices. Advantages of midfield systems include superior T_1 -dependent contrast, fewer problems with chemical shift, susceptibility effects, and certain motion artifacts. Narrowing the

Table 3 Imaging of Intracranial Hemorrhage on Midfield MRI.^{18,19}

Stage	Composition ^a	Signal intensity and optimal sequences ^b
Hyperacute (<24 h)	Fresh blood	Hyperintense + on T_1 WIs Hyperintense +++ on STIR, $>T_2^*$ WIs $>T_2$ WIs
Acute (1–3 days)	DeoxyHb in intact RBCs	Hypointense + on T_1 WIs, Hypointense +++ on T_2 WIs, GRE $>$ SE
Subacute (4–7 days)	DeoxyHb in lysed RBCs	Hyperintense +++ on T_1 WIs Hypo- to hyperintense on T_2 WIs
Chronic (1–3 weeks)	MetHb	Hyperintense on T_1 WIs Hyperintense on T_2 WIs, GRE $>$ SE

^bWIs, weighted images; IR, inversion–recovery; SE, spin echo; +, mild; +++, marked.

bandwidth at midfield increases the S/N and is a strategy used to improve image quality towards that of high-field systems where the concomitant increase in chemical shift is tolerable. The theoretical reduction in rf power deposition at midfield will become of practical interest with the use of MTC imaging and fast spin echo techniques.

6.2 Craniospinal MRI

When systems with hardware and software specifications that are virtually identical apart from field strength are compared, image S/N is greater at 1.5 T than at 0.5 T, but there is no significant change in diagnostic accuracy for head and spine imaging between the two field strengths.¹⁷ Most conditions, such as cerebrovascular disease and tumors, have similar signal intensity characteristics at mid and high field. A notable exception is the appearance of intracranial hemorrhage, which depends on the stage of evolution of the hematoma as well as the field strength of the MR scanner used (Table 3).^{18,19}

Twelve to 24 h after an intracranial bleed, acute hematoma containing oxyhemoglobin is most readily detected on midfield MRI using T_2^* -weighted GRE sequences or a short τ inversion–recovery (STIR) sequence which takes advantage of the combination of high proton density and relatively long T_1 relaxation time of fresh blood. Subsequent T_2 shortening due to deoxyhemoglobin formation is more easily demonstrated on T_2^* -weighted GRE than T_2 -weighted SE sequences at midfield strength. As deoxyhemoglobin converts to methemoglobin, paramagnetic T_1 shortening results in hyperintensity on T_1 -weighted sequences. Visibility of low signal intensity due to T_2 shortening is maximized on T_2^* -weighted sequences. When hemolysis occurs after about 7 days, hematoma becomes hyperintense on all sequences.

Comparative studies have demonstrated that midfield MR is more sensitive than CT in detecting both hemorrhagic and non-hemorrhagic lesions resulting from closed head trauma, with the exception of subarachnoid hemorrhage.²⁰ The greater sensitivity of high-field MRI to magnetic susceptibility confers a theoretical advantage for demonstrating acute hemorrhage. In practice, selection of appropriate pulse sequences at midfield strength, i.e. heavily T_2 -weighted SE or T_2^* -weighted GRE sequences to maximize differences in susceptibility, compen-

sates for field strength differences. Similarly, acute hemorrhagic contusion of the spinal cord can be demonstrated at midfield, using T_2^* -weighted GRE sequences to detect the susceptibility effects of deoxyhemoglobin. In a clinical setting, imaging of high dependency patients requiring ventilation or close monitoring is more easily achieved at midfield than high field. Specific circumstances where high field strength may be advantageous in craniospinal MRI include high resolution imaging, for example of the pituitary gland, and demonstration of brain iron.

6.3 Extracranial Head and Neck MRI

Many studies evaluating MRI for the demonstration and staging of tumors in the maxillofacial region and anterior neck have been performed at midfield strength. MRI of small structures such as the parathyroid glands has been successful at both mid and high field. The need to obtain thin slices with high spatial resolution confers some advantage on high field MRI, but images of diagnostic quality are achievable at field strengths of 0.35–0.5 T. The use of surface receiver coils specifically designed for anterior neck imaging overcomes the handicap of reduced S/N at midfield strength, and image quality is high due to relatively little motion or chemical shift artifacts.

6.4 Cardiovascular MRI

Much of the early experience of cardiovascular MRI was at midfield strength, typically employing T_1 -weighted SE sequences gated to the cardiac cycle to provide anatomic information in congenital and acquired cardiovascular disease. Cardiac gated fast SE sequences are now also available at midfield strength; uses include the demonstration of cardiac and paracardiac masses, myocardial disease, and anomalies of the great vessels such as aneurysms and stenosis. Phase contrast sequences providing flow information are also readily available at midfield strength, providing semiquantitative flow information in conditions such as valvular heart disease and coarctation of the aorta. High-field MRI scanners offer increased S/N in the body coil and very fast sequences, thus effectively freezing cardiac motion and enabling ‘real-time’ stu-

dies of cardiac motion to be performed. Monitoring equipment may be more difficult to use in the proximity of a high field strength magnet however, and cardiac-gated acquisitions may be more difficult to set up than at midfield strength. Chemical shift artifacts mimicking intraluminal disease, e.g. dissection flaps, are more troublesome at high field strength, as are susceptibility artifacts in the postoperative patient. MR angiography of the coronary arteries is more successful at high field strength where the ability to reduce voxel size while maintaining the S/N is crucial. Routine display of larger visceral and peripheral vessels, however, is possible using commercially available software and receiver coils on midfield MR scanners.

6.5 Musculoskeletal MRI

There is no important advantage of high-field MRI over midfield MRI when evaluating bone and soft tissue tumors, trauma, or inflammation. Indeed, the greater degree of chemical shift and susceptibility effects may be deleterious to image quality. The availability of specific surface receiver coils for imaging joints and small peripheral body parts usually overcomes the potential problem of inadequate signal at midfield strength. The exception may be high-resolution imaging of small structures; studies have demonstrated a significant increase in accuracy for imaging the medial meniscus at 1.5 T compared with imaging at 0.35 T ($p < 0.0002$).²¹ No significant difference was demonstrated between field strengths for imaging the lateral meniscus or cruciate ligaments. More recent studies however, have shown no clinically significant field strength dependent difference between 0.5 T and 1.5 T systems for diagnosis of internal derangements of the knee.²²

6.6 Abdominal MRI

The convergence of T_1 relaxation times for normal liver parenchyma and neoplasm with increasing field strength renders T_1 -weighted SE imaging at high field strength less sensitive to focal liver pathology than low or midfield MRI. Hepatic tumors are also demonstrated using heavily T_1 -weighted inversion-recovery (IR) sequences or T_2 -weighted sequences. Using these sequences, there is no significant difference in the ability of 0.5 and 1.5 T MRI systems to detect focal hepatic lesions.^{23,24}

Measured relaxation times for normal and pathological tissues vary between mid- and high-field MRI systems. Magnetic susceptibility effects tend to increase as the square of the field strength, resulting in relative shortening of the observed T_2 relaxation time at high field. Variability will also be introduced by individual and lesional differences, the specific MRI system and pulse sequences used, and the method of calculation. However, statistically significant differences in calculated T_2 values have been demonstrated between normal liver and tumor, and between hepatocellular carcinoma and cavernous hemangioma imaged at both 0.35 and 1.5 T.²⁵ No significant differences in focal liver lesion detection can be demonstrated between 0.2 and 1.5 T systems when using T_2 -weighted sequences enhanced by intravenous superparamagnetic iron oxide contrast medium.²⁶

In abdominal MRI, conventional SE sequences are often degraded by movement artifacts. Very fast GRE sequences allowing breath-hold imaging of abdominal structures, which

effectively freeze respiratory motion, are available on midfield systems. Although motion artifact is reduced, contrast on the fast sequences is relatively poor, and such dynamic MRI sequences are usually acquired in conjunction with a bolus of intravenous paramagnetic contrast agent. Maximum intensity pixel (MIP) reconstructions from this type of acquisition produce an elegant display of portal venous anatomy. The combination of very fast GRE sequences with steady state precession allows MIP projections of the main bile ducts and peripheral biliary tree.

In pancreatic imaging the lack of a reliable gastrointestinal contrast agent limits the ability of MRI to delineate the margins of the gland distinctly from adjacent small bowel. Contrast between pancreas and retroperitoneal fat may be poor, particularly when fatty involution of the gland is present. Solid pancreatic masses can be very similar in signal intensity to normal parenchyma on both T_1 - and T_2 -weighted sequences, and the inability of MRI to identify calcification is a disadvantage when attempting to characterize pancreatic masses. Spatial resolution is also currently less than is possible with CT. MR image degradation from motion artifacts due to respiration, peristalsis, and vascular pulsation are less of a problem at midfield than high field. Breath-hold sequences can overcome some motion artifacts, but the intrinsically poor soft tissue contrast of the GRE sequence on which they are based does not improve detection of small pancreatic masses, unless gadolinium enhancement with fat suppression is used. The results of studies assessing the ability of midfield MRI to identify pancreatic tumors and inflammation have been encouraging. Solid pancreatic carcinomas are demonstrated as an area of low signal intensity on T_1 -weighted and medium signal intensity on T_2 -weighted SE sequences at 0.5 T, whereas a very high signal intensity is seen on T_2 -weighted sequences of cystadenocarcinomas.²⁷ Islet cell tumors less than 2.5 cm in diameter can be successfully localized using T_1 - and T_2 -weighted sequences.²⁸ In severe acute pancreatitis, contrast-enhanced fast GRE MRI at 1.0 T is equivalent to CT in determining pancreatic viability.²⁹

MRI has a limited role in demonstrating renal masses, and the potential for characterizing renal tumors and differentiating between small benign and malignant lesions has not yet been realized at midfield strength. Results have been more encouraging using higher field strength systems, breath-hold imaging, dynamic contrast enhancement, and fat suppression. Studies of the adrenal glands performed at midfield strength (0.35–0.5 T) have analyzed signal intensity ratios of adrenal masses, and claim the ability to separate a proportion of benign and malignant adrenal masses on the basis of their signal intensities or calculated relaxation times. No consistent difference in the signal intensity of adrenal adenomas and malignant adrenal tumors has been demonstrated with T_1 - or T_2 -weighted sequences at 1.5 T (using fat or liver tissue as the internal reference). Calculated T_2 values may be more helpful, a calculated T_2 value of 65 ms or greater being associated with malignancy.³⁰

6.7 Pelvic MRI

Staging of pelvic malignancy is useful in carcinoma of the body of the uterus, the uterine cervix, bladder, and rectum. It may also help to differentiate between recurrent pelvic tumor

and the effects of previous surgery or radiotherapy. Good results have been achieved using MRI, both at midfield and high field strengths. The S/N at all field strengths is improved by the use of a pelvic surface coil, e.g. of Helmholtz design, or by using multiple phased array coils. Motion artifacts due to respiration are less of a problem in the pelvis than in the upper abdomen, but the effects of peristalsis, vascular pulsation, chemical shift, and susceptibility are important causes of reduced image quality, their effects being greater at high field than at midfield. Endoluminal MRI is available at the end of the 1990s at both midfield and high field and offers the prospect of improved accuracy of prostate cancer staging over body coil imaging.

7 SUMMARY

There is little objective evidence of a substantial difference in diagnostic accuracy between MR images obtained at midfield or high field. Image quality depends more on using a modern scanner which is maintained to specification by means of a routine quality assurance program, and the use of appropriate pulse sequences by experienced personnel. Studies of machines of different field strength using test objects have shown wide variability in performance between machines of the same field strength and of individual systems at different times due to variable quality assurance. For certain diagnostic applications, the relatively good tissue contrast and easier operation of midfield systems may be preferable to the higher S/N and spatial resolution of high-field systems. Very fast GRE sequences obtained at 1.5 T are available at 1.0 T but do not necessarily reduce the overall examination time, which includes the time necessary to prepare the patient for scanning.

Jane M. Hawnaur. b 1957. MBChB, 1981, MRCP, 1984, DRMD, 1987, FRCR, 1987. Senior lecturer in Radiology, University of Manchester, 1991–present, and Honorary Consultant Radiologist, Central Manchester Healthcare Trust. Clinical radiologist, with research interest in MRI in oncology.

Ian Isherwood. b 1931. MBChB, 1954, DMRD, 1957, FFR, 1960, FRCR, 1975, FFR RCSI (Hon.), 1980, FRCP, 1986, Honorary MD, University of Zaragoza, 1986, CBE 1996. Emeritus Professor of Radiology, University of Manchester.

MRI in Clinical Medicine

Fergus V. Coakley and Alexander R. Margulis

University of California, San Francisco, CA, USA

Magnetic resonance imaging (MRI) is the third and most recently developed of the major cross-sectional imaging techniques. MRI entered clinical usage in 1980, well after ultrasonography and computed X-ray tomography. MRI has revolutionized radiology by greatly extending the soft tissue contrast resolution of conventional imaging techniques. Clinical MRI was introduced in Nottingham and Aberdeen, and this was followed in 1981 by high-quality images from the Hammersmith Hospital, the Cleveland Clinic, the Massachusetts General Hospital, and the University of California, San Francisco.¹⁻¹⁰ At that time, ultrasound was the most common and most readily available cross-sectional modality, while computed tomography (CT) was regarded as the pre-eminent imaging technique: CT sections of the body were obtainable with an acquisition time of 5-6 s each. Despite these established alternative imaging modalities, the diagnostic advantages of MRI were apparent from the very beginning. Starting in 1981, all meetings where MRI reports were presented attracted overflowing audiences.

What particularly captured the interest of the physicians in these audiences was the soft tissue contrast resolution of MRI, the ability to image in any plane, the wide field of view, the rapidly improving quality of the images, the ability to visualize blood vessels because of the effects of flow, and, above all, the dependence of the method on many variable physical parameters offering a never-ending number and variation of sequences and coil improvements. All of these advantages provided for better lesion detection and characterization and greater speed of imaging. In addition, sequences could be manipulated to suppress many artifacts, such as those owing to respiratory motion, cardiac and arterial pulsatility, eddy currents and chemical shift.¹¹⁻¹⁴ An important later advance was the development of intravenously administered MR contrast media which are even safer than the iodinated intravascular contrast media used in conventional radiography and CT. The versatility of the method is manifested by the vast array of instruments that have been available since the early stages of clinical MRI. Images of acceptable quality can be generated from permanent, resistive or superconducting magnets, with field strengths varying from 0.03 to 1.5 T. Higher field strength scanners of up to 3-4 T are available for investigational and animal studies. Because of its many advantages, MRI rapidly became a popular and widely accepted imaging tool in developed countries, particularly the United States and Japan, and later in western Europe. The number of MRI scanners in the United States in 1997 was 3670, or 13.85 per million population. Differences in the availability of MRI scanners is largely a consequence of government and state control over the proliferation of high-cost procedures and technology and does not relate to the desires of either physicians or patients. For example, the number of MRI scanners in California in 1997

was 55 per million population, while in Massachusetts, a state that requires certificates of need, the number was 13 per million population. In the United States, most of the MRI scanners have a field strength of 1.5 T. In the rest of the industrialized world, notably Japan and western Europe, 0.5 to 1 T instruments predominate. In 1997, MRI had a 21% share of all global medical imaging expenditure. By comparison, conventional radiography had a 34% share. CT and nuclear medicine had a comparatively minor share of the global imaging expenditures.¹⁵⁻¹⁸

Until the late 1980s, the main clinical applications of MRI were in the brain and spine. In these anatomic regions, MRI was superior to other imaging modalities mainly because of the relative lack of motion. As the number of MRI scanners increased, and with the development of motion suppression, faster sequences, and fat suppression, other anatomic regions started to be imaged routinely. A further contributory factor to the growth in interest in non-neurological applications of MRI was the emergence of a cadre of body-imaging radiologists who were adequately trained in the performance and interpretation of MRI. These factors resulted in a spectacular increase in the application of MRI to areas other than the brain and spine in the United States. For example, between 1991 and 1997, the total increase in the use of MRI was a startling 81%. When examined by system, chest imaging rose 88%, brain imaging rose 78%, spinal imaging rose 61%, and general abdominal imaging rose 57%. However, pelvic imaging decreased by 19%. Despite the disproportionately greater rise in non-neurological applications, the absolute number of studies remained higher for neurological examinations. For example, in 1997, the number of brain and spinal MRI studies performed in the United States was 8 032 000, compared with 199 000 abdominal studies, and 109 000 chest studies. The number of pelvic MRI was a relatively modest 130 000.

By the 1990s, MR had become the primary imaging technique for diseases of the brain, head and neck, major blood vessels, spine, musculoskeletal system, and pelvis, including the male and female reproductive organs.

MRI with intravenously administered Gd-DTPA has essentially replaced contrast-enhanced CT in the diagnostic evaluation of brain tumors, stroke, and multiple sclerosis (Figures 1 and 2).¹⁹⁻²¹ MRI has not yet been able to demonstrate specific diagnostic findings in Alzheimer's disease, and it is often unable to identify accurately the source of focal epileptic seizures.

In the head and neck,²² MRI is outstanding in showing parathyroid and thyroid neoplasms, tumors of salivary glands, enlarged lymph nodes, and tumors of the upper air passages.^{13,14} It is also valuable in diagnosing brachial plexus injuries. In the musculoskeletal system, MRI is the optimal modality for studying degenerative, inflammatory and trauma induced changes in the spine²²⁻²⁴ and major joints: the knee, hip, shoulder.²⁵⁻²⁷ As experience increases, smaller joints in hand and foot are being examined with MRI and the findings guide therapy. MRI is also the best method for the evaluation of bone and soft tissue tumors. With newer techniques, it is very promising in the evaluation of different types of arthritis (Figure 3).

In the male pelvis, MRI is used predominantly for staging cancer of the prostate (Figure 4) and the evaluation of major trauma prior to definitive surgical repair. MRI of the prostate is

Figure 1 Spin-echo T_1 -weighted coronal MR image of the brain, showing marked enhancement of a left lateral geniculate glioma

generally not used for cancer diagnosis but rather for local and regional staging of biopsy-proven cancer. Assessment of extracapsular extension, seminal vesicle invasion, and lymphadenopathy are critical observations in staging prostate cancer and can all be assessed with relatively high accuracy by MRI. The addition of magnetic resonance spectroscopy to routine clinical MRI of the prostate can also help in tumor evaluation.^{28–31}

In the female pelvis, MRI is used for the staging of tumors of the endometrium (Figure 5), cervix uteri, ovaries, and

Figure 2 Spin-echo T_1 -weighted axial MR image of the posterior fossa, before (left) and after (right) intravenous administration of Gd-DTPA. An enhancing small left acoustic neuroma (arrow) is evident. The use of Gd-DTPA helps in lesion detection

Figure 3 Saturation-transfer subtraction axial MRI section of the knee of a patient with nonspecific synovitis. The image was generated by subtracting T_2 -weighted steady-state gradient-echo images without an on-resonance pulsed saturation transfer from the same sequence obtained with a pulsed saturation transfer. Patellar cartilage can be clearly distinguished from adjacent joint fluid and subchondral bone. Hypertrophic synovial tissue is sharply delineated, without the use of intravenous gadolinium-containing contrast media. The patient subsequently underwent surgical synovectomy.

vagina. Intravenous Gd-DTPA is helpful in staging most gynecologic malignancies, with the exception of cervical cancer.³¹ The use of Gd-DTPA is usually only helpful in cervical cancer when there is suspected invasion of adjacent organs, tumor necrosis, or post-radiation change.

In the heart, MRI can diagnose and evaluate various types of congenital and valvular heart disease.^{32–35} However, cardiac applications of MRI remain relatively limited because of a lack of enthusiasm for the technique among most cardiologists and

Figure 4 Fast spin-echo T_2 -weighted axial MR image of the prostate, obtained using an endorectal coil. Invasion of the right seminal vesicle (arrow) by carcinoma of the prostate is seen

Figure 5 Fast spin-echo T_2 -weighted sagittal MR image of the uterus, showing a large cervical carcinoma (arrow) with deep cervical stromal invasion and extension above the internal os into the uterine body

because of the relatively small number of cardiac radiologist-investigators. Major breakthroughs in the area of cardiac MRI are likely in the coming years, as ultrafast sequences and strategies to overcome image degradation by cardiac motion continue to evolve.

Although CT is still the principal imaging method for demonstrating renal abnormalities, MR with Gd-DTPA is becoming at least as accurate.³⁶ MRI may be preferable in patients with an elevated creatinine or a history of previous reactions to iodinated contrast. MRI may also be helpful in assessing vascular invasion in renal cell carcinoma.

MRI is extremely useful in the detection and characterization of focal liver lesions (Figure 6). Initially, dynamic Gd-

DTPA-enhanced MRI appeared inferior to CT arteriography, but more recent results with improved technology suggest that the two techniques are of comparable overall accuracy. MRI may be slightly less sensitive but more specific than CT arteriography, when intraoperative exploration and ultrasound are used as the standard of reference. Newer specific contrast media such as Mn-DPDP and superparamagnetic iron oxide particles have recently become available. These agents may help in lesion detection and characterization, although a definite advantage over the standard use Gd-DTPA has not been demonstrated.³⁷⁻⁴¹ In the future, optimized use of such newer contrast agents is likely to be more rewarding. A relatively recent application of MRI in the liver is the use of ultrafast T_2 -weighted sequences to image the fluid in the biliary and pancreatic ducts. This technique of MR cholangiopancreatography appears set to replace diagnostic endoscopic retrograde cholangiopancreatography in the next few years (Figure 7).

MRI has established at least an equality with other imaging techniques in the examination of the heart, mediastinum, retroperitoneum, and for focal lesions of the spleen.¹¹⁻¹⁴ MRI is still inferior to CT in the evaluation of the gastrointestinal tract and its mesentery.^{42,43} This may change very shortly with shorter sequences and the use of antiperistaltic agents such as glucagon.⁴⁴ Interesting advances are also being made in the examination of the lung, particularly in the evaluation of pulmonary edema, embolism, and fibrosis.⁴⁵⁻⁴⁷ More recently, there has been considerable interest in the use of inhaled hyperpolarized ^3He or ^{129}Xe to produce images of lung ventilation.⁴⁸ Currently, MRI is as limited as CT in the evaluation of tumor involvement of lymph nodes, although it is very likely that with new contrast media this difficulty may be overcome.

Recently, MRI of the breast combined with the intravenous use of Gd-DTPA has shown great promise by being more sensitive in discovering cancer in dense breasts than conventional X-ray mammography. Dramatic progress has been made since MR mammography was first described in the early 1980s, although many questions remain unanswered. The development of better and more specific contrast agents is likely to be the

Figure 6 In phase (a) and out of phase (b) fast spoiled gradient-echo T_1 -weighted axial MR image of the liver, showing a large irregular lesion in the right hepatic lobe. The lesion has markedly reduced signal intensity on the out of phase image (b), confirming the presence of fat and establishing the diagnosis of focal fatty infiltration. A prior CT image had been interpreted as suggestive of malignancy

Figure 7 Single-shot fast spin-echo T_2 -weighted coronal MR cholangiopancreatography in a patient with pancreas divisum. The main pancreatic duct is seen draining to the minor papilla (arrow) at a level superior to the entry of the common bile duct to the major papilla. The image was generated as a maximum-intensity projection of a slab of multiple contiguous thin coronal sections through the pancreaticobiliary tree

Figure 8 Gradient-echo T_1 -weighted sagittal MR image of the breast after the intravenous administration of Gd-DTPA, with fat suppression. This MR mammogram shows a small enhancing carcinoma (arrow). The lesion was not detected using conventional radiographic mammography

next major advance. A practical system of MRI-guided breast biopsy is also essential, especially for those lesions that are seen only on MRI and not evident on conventional radiographic mammography or ultrasound (Figure 8). Better coils and low-cost dedicated equipment are also required.⁴⁹⁻⁵²

MRI of the fetus has been slow to develop, because of image degradation by fetal motion and the need for high spatial resolution. The recent development of ultrafast spin-echo based T_2 -weighted sequences has been a major advance, and fetal imaging is emerging as one of the more exciting new clinical applications of MRI. The use of fetal MRI remains confined to those cases where antenatal ultrasound is indeterminate or inconclusive, since in most cases ultrasound is an adequate study. In difficult situations, MRI can provide significant incremental information (Figure 9) and impacts on management in a substantial proportion of patients.^{53,54}

The field of MRI has also advanced with the construction and application of a multitude of surface coils, single or assembled in phased arrays, sometimes in conjunction with

Figure 9 Single-shot fast spin-echo T_2 -weighted MR image of a fetus with suspected laryngeal atresia from a prior sonograph, in an oblique longitudinal plane relative to the fetus. The constellation of diaphragmatic eversion (white arrows), a large volume of fetal ascites (asterisk), marked subcutaneous edema (black arrow), and a blind-ending fluid-filled upper airway (curved white arrow) is diagnostic of laryngeal atresia. The fetus was successfully treated by in utero tracheostomy

Figure 10 Gradient-echo flow-sensitive axial MR time-of-flight angiogram in a patient with a large arteriovenous malformation. The image was generated as a maximum-intensity projection of a slab of multiple contiguous thin axial sections through the circle of Willis

endoluminal coils such as with the endorectal coil used for examination of the prostate (Figure 4).³⁰

MR angiography has rapidly advanced since it was first introduced in the late 1980s. Initially, MR angiography was limited by relatively long acquisition times and low spatial resolution. These problems have been largely overcome by improvements in hardware, pulse sequence design, and sequencing strategies. MR angiography is increasingly used in the evaluation of arterial and venous disease throughout the body, especially in patients who have contraindications to conventional angiography, such as renal impairment, iodinated contrast allergy, and coagulopathy. MR angiographic techniques may be based on time of flight (Figure 10), phase contrast, black blood, or contrast enhancement. Magnetization transfer can be used to suppress signal from stationary tissue approaches. Recently, first-pass gadolinium-enhanced MR angiography has received considerable attention. In the future, the emergence of blood pool contrast agents is likely to contribute further to the development of MR angiography. This technique, with its noninvasive nature and ease of performance, is already a clinical procedure in the evaluation of major vessels in the brain, neck, body, and extremities.⁵⁵⁻⁵⁸ Imaging of the coronary arteries with a resolution equivalent to conventional angiography remains a crucial goal that has not yet been achieved. Coronary MR angiography poses unique challenges because of rapid motion and the small size of the vessels. Cor-

onary MR angiography is the 'holy grail' of clinical MRI, but despite the technical problems is likely to become clinically available in the first decade of the 21st century. Techniques for the evaluation of the proximal segments of the major coronary arteries already exist. Clinical acceptance requires the procedure to produce diagnostic images in a cost-effective manner. Improved contrast agents may be needed.³⁵

Interventional MRI units are being feverishly developed. These interventional units vary greatly in design and cost. Permanent magnets with wide separation allowing manipulation, a resistive magnet with four ports to provide good field homogeneity and allow ample access, and a unit with two separated tunnels (the separation to permit space for the surgeon to work), are all at various stages of completion. These units will significantly differ in cost. The quality of the image, the speed of acquiring the image, the size and weight of the units, and shielding requirements will all play a significant role in clinical acceptance. Interventional MRI requires MR-compatible instruments and anesthesia equipment. Better techniques for MRI tracking of guidewires and catheters are also needed. Initially, interventional MRI is likely to be most useful in the evaluation of interstitial therapies such as laser treatment, radiofrequency ablation, and cryosurgery.⁵⁹ It remains to be seen how the roles

Figure 11 Diffusion-weighted axial MR image in a patient with an acute right hemiparesis. Increased signal (arrow) in the distribution of the left middle cerebral artery territory confirms the diagnosis of cerebral infarction

Figure 12 MR spectroscopy performed in a patient with prostate cancer. The T_2 -weighted fast spin-echo axial image of the prostate shows an area of reduced signal intensity in the right peripheral zone. The corresponding MR spectra demonstrate elevation of choline and reduction of citrate in this area, confirming the presence of malignancy. Normal data, obtained from the healthy part of the gland, are shown for comparison and demonstrate a high level of citrate and no detectable choline

of radiologists, surgeons, anesthesiologists, and other health care professionals will develop in this complex field.

Advances in the basic sciences and continued improvements in hardware and software have resulted in an increasing array of MRI techniques capable of evaluating physiological rather than anatomical information. Such techniques include diffusion MRI, perfusion MRI, functional MRI, MR spectroscopy, MR thermography, and MR elastography.^{11–14} Diffusion MRI has been used mainly in the assessment of brain disease, because disruption in the regular three-dimensional configuration of nerve fibers results in marked alterations in the local pattern of molecular diffusion. Diffusion MRI has become clinically useful in the diagnosis of stroke, because diffusion abnormalities can be detected in the earliest stages of a cerebral infarct (Figure 11) at a time when other imaging techniques are often nondiagnostic and when thrombolytic therapy still has the potential to improve outcome.⁶⁰ Diffusion MRI may also be

helpful in locating epileptogenic foci prior to neurosurgical treatment.⁶¹ Perfusion MRI utilizes exogenous or endogenous contrast to measure blood flow at the capillary level and in the future may have clinical applications in the brain, heart, and kidneys.⁶² Functional MRI utilizes focal changes in blood volume, flow, or oxygenation to produce images that reflect local organ function. Functional MRI has been used predominantly to map the spatial and temporal distribution of neuronal activity in the brain during specific cognitive, motor, or sensory tasks.⁶³ MR spectroscopy utilizes the slight differences in Larmor frequency between protons in different molecules to assess the level of different proton-containing tissue metabolites. Clinical applications are emerging in tumors of the breast, prostate (Figure 12), and brain.^{30,64,65}

Many of the current and future developments in MRI will be accompanied and augmented by the introduction of new MR contrast media. Such new contrast media are likely to

Figure 13 A resistive 0.5-T MR imager transported through a narrow doorway and later assembled in room, making siting much more economical

evolve along the following lines.⁶⁶⁻⁷⁰ (a) High-molecular-weight contrast media will be useful for perfusion and blood-pool MRI techniques, since these remain in the circulation. (b) Tissue-specific contrast agents, which enhance only a single organ or tissue type, will increase the ability to detect and characterize lesions. Such contrast media are already available, for example the manganese-based contrast media that are picked up and excreted by hepatocytes and the ferumoxides that are taken up by reticuloendothelial cells. (c) Contrast media that exit the capillaries and enter the lymphatic system to be picked up by lymph nodes will increase the ability to detect and characterize lymph node abnormalities. (d) Contrast media enveloped in liposomes can be designed for uptake by different targeted organ systems, for example the bone marrow. (e) Contrast media incorporated with monoclonal antibodies may provide the ultimate 'magic bullet' for imaging of targeted abnormal cells, for example cancer cells.

Cost remains a major hurdle to the greater availability and use of clinical MRI in much of the world. As competition between companies grows and the marketplace becomes increasingly global, a vast array of scanner types is emerging. Scanner technology now includes permanent magnets, resistive magnets (Figure 13), and various types of superconductive magnet. These different machines allow considerable choice in the degree of sophistication and cost, so that small dedicated

scanners are available to purchasers who do not have the resources to acquire an expensive high-field-strength multipurpose scanner. This wide choice helps make MRI more widely available. Almost all scanners have the potential to be upgraded. The size of scanners and extent of fringe fields is being reduced, making siting less expensive. As governments realize that MRI is cost effective, the clinical use of MRI will be expanded and encouraged. However, strict regulation of reimbursement for MRI studies will undoubtedly become universal.¹⁸ Such regulations already exist in many parts of the industrialized world.

MRI offers an unparalleled choice of techniques for the imaging of normal and abnormal anatomy and pathology. Current and future developments in MR contrast media are likely to expand the clinical utility of MRI still further. The complexity of MRI and the necessity to be familiar with anatomy in all planes and all body parts makes MRI a more difficult diagnostic modality to master than any other imaging technique. As a result, for optimal MRI performance and interpretation, clinical expertise and technical proficiency are essential. The radiological community must continue to maintain a strong influence over clinical standards in MRI.
